Oral and Maxillofacial Surgery

Oral and Maxillofacial Surgery

Edited by

Lars Andersson

DDS, PhD, DrOdont
Professor, Oral & Maxillofacial Surgery
Chairman Department of Surgical Sciences
Faculty of Dentistry
Health Sciences Center
Kuwait University
Kuwait

Karl-Erik Kahnberg

DDS, PhD, DrOdont
Professor Emeritus, Oral and Maxillofacial Surgery
Institute of Odontology
The Sahlgrenska Academy
University of Gothenburg
Sweden

M. Anthony (Tony) Pogrel

DDS, MD, FRCS, FACS, Associate Dean for Hospital Affairs
Professor and Chairman, Department of Oral and Maxillofacial Surgery
University of California, San Francisco
USA

This edition first published 2010
© 2010 Blackwell Publishing Ltd

Blackwell Publishing was acquired by John Wiley & Sons in February 2007. Blackwell's publishing programme has been merged with Wiley's global Scientific, Technical, and Medical business to form Wiley-Blackwell.

Registered office

John Wiley & Sons Ltd, The Atrium, Southern Gate, Chichester, West Sussex, PO19 8SQ, United Kingdom

Editorial offices

9600 Garsington Road, Oxford, OX4 2DQ, United Kingdom
2121 State Avenue, Ames, Iowa 50014-8300, USA

This publication is designed to provide accurate and authoritative information in regard to the subject matter covered. It is sold on the understanding that the publisher is not engaged in rendering professional services. If professional advice or other expert assistance is required, the services of a competent professional should be sought.

Library of Congress Cataloging-in-Publication Data

Oral and maxillofacial surgery / edited by Lars Andersson, Karl-Erik Kahnberg, M. Anthony (Tony) Pogrel.
p. ; cm.

Includes bibliographical references and index.

Summary: "Oral and Maxillofacial Surgery is the comprehensive reference for all trainees and specialists in oral and maxillofacial surgery, oral surgery and surgical dentistry, including the current research, practice and developments in the field as expressed by world authorities. The Editors are joined by over 50 international experts, offering a truly global perspective on the full spectrum of issues in oral and maxillofacial surgery. The book's coverage extends from basic principles such as patient evaluation, dental anesthesia, wound healing, infection control and surgical instruments to coverage of the complex areas of dentoalveolar surgery, oral pathologic lesions, trauma, implant surgery, dentofacial deformities, temporomandibular joint disorders and salivary gland disorders." —Provided by publisher.

ISBN 978-1-4051-7119-9 (hardback)

1. Mouth--Surgery. 2. Maxilla--Surgery. 3. Face--Surgery. I. Andersson, L. (Lars), 1950–
II. Kahnberg, Karl-Erik. III. Pogrel, M. Anthony.

[DNLM: 1. Oral Surgical Procedures—methods. 2. Face—surgery. 3. Stomatognathic System—surgery.

Part 1 Basic Principles

1

Section Editor: Tony Pogrel

1	Patient Evaluation	3
	<i>Alan S. Herford and Wayne K. Tanaka</i>	
	Obtaining a patient history	3
	Physical examination	5
	Comorbidities/systemic diseases	6
	Cardiovascular system	6
	Pulmonary system	9
	Endocrine system	10
	Obesity	11
	Other organ systems	11
	Imaging	12
	Laboratory studies	12
	Arriving at a diagnosis	14
	Assessing anesthetic/surgical risk	14
	Office vs inpatient	14
	Summary	15
	References	15
2	Radiographic Imaging in Oral and Maxillofacial Surgery	17
	<i>Arne Petersson</i>	
	Introduction	17
	Computed tomography (CT)	17
	Cone-beam computed tomography (cone-beam CT)	18
	Magnetic resonance imaging (MRI)	18
	Impacted teeth	18
	Pathological conditions – inflammatory lesions, cysts, benign and malignant tumors	18
	Inflammatory lesions	18
	Cysts and benign tumors	21
	Malignant tumors	22
	Temporomandibular joint (TMJ)	24
	Implant treatment	25
	References	27
3	Medical Aspects – High-risk Patients	29
	<i>Earl G. Freymiller</i>	
	Cardiovascular system	29
	Ischemic heart disease	29
	Valvular heart disease	30
	Congestive heart failure	31
	Respiratory system	31
	Asthma	31
	Chronic obstructive pulmonary disease	32
	Renal system	32
	Renal failure	32
	Endocrine system	32
	Diabetes mellitus	32

Gastrointestinal system	33
Liver failure	33
Hematologic system	33
Disorders of hemostasis	33
Immunologic system	34
HIV / AIDS	34
Neurologic system	35
Seizure disorders	35
Cerebrovascular accident	35
Musculoskeletal system	36
Bisphosphonate-related osteonecrosis of the jaws (BRONJ)	36
References	36
 4 Medical Emergency Care	 39
<i>Zachary S. Peacock and M. Anthony Pogrel</i>	
Syncope	40
Management	40
Chest pain	40
Pathogenesis	40
Diagnosis and history	41
Management	41
Cardiac arrest	42
The automated external defibrillator	42
General approach to the collapsed patient	43
Considerations in transfer of the patient	43
Asthma	43
Pathophysiology	43
Prevention	43
Clinical presentation	44
Management	45
Hypoglycemia	45
Normal physiological response to hypoglycemia	45
Signs and symptoms of hypoglycemia	46
Management	46
Anaphylaxis	47
Presentation	47
Differential diagnosis	48
Management	48
Seizures	48
Management	48
Status epilepticus	49
References	49
 5 Local Anesthesia	 51
<i>John Gerard Meechan</i>	
Introduction	51
Mode of action of local anesthetics	51
Techniques of local anesthesia for oral and maxillofacial surgery	52
Topical anesthesia	52
Infiltration anesthesia	52
Regional block anesthesia	52
Supplementary intraoral techniques of local anesthesia	56
Local anesthetic drugs	57
Lidocaine	57
Mepivacaine	57
Prilocaine	57
Articaine	57
Etidocaine	58

	Bupivacaine	58
	Levobupivacaine	58
	Ropivacaine	58
	Complications of local anesthesia in the orofacial region	58
	Localized complications	58
	Systemic complications	59
	References	60
6a	Sedation and General Anesthesia in Oral and Maxillofacial Surgery: A UK Perspective	61
	<i>C. Michael Hill</i>	
	History	61
	The role and scope of sedation	63
	Inhalational sedation	64
	Oral sedation	65
	Intravenous sedation	65
	General anesthesia	67
	Conclusion	68
	References	68
6b	Sedation and General Anesthesia in Oral and Maxillofacial Surgery: A US Perspective	69
	<i>Richard C. Robert</i>	
	Historical perspective	70
	The 19th century after Wells and Morton	70
	The 20th century	72
	The 21st century	75
	Training, professional organizations, and standards	75
	Goals and objectives in the administration of anesthesia	76
	The initial intuitively derived concepts	76
	The initial approach	77
	Requisites for the ideal anesthetic in the modern era	77
	The essential role of the basic sciences in the advancement of anesthesia	77
	Areas of the brain affected by anesthetic agents	77
	The critical realization that on a molecular basis all anesthetic drugs share a common mechanism of action	81
	Multiple sites of action and receptors in the CNS dictate a balanced approach	86
	The current status of office anesthesia in the oral and maxillofacial surgery practice	87
	Primary anesthetic agents	87
	Ancillary agents	92
	Balanced anesthetic approaches currently used in oral and maxillofacial surgery practices	96
	Method of delivery	97
	Total intravenous anesthesia (TIVA)	97
	The author's office-based anesthesia technique	98
	Intravenous sedation	98
	Local anesthesia	98
	Perioperative management	101
	Preoperative preparation	101
	Delivery system	103
	Airway management	104
	Monitoring	105
	Awareness during anesthesia	108
	Intraoperative fluid management	108
	Recovery and discharge	109
	Special patient populations	109
	Future trends and advancements – on the horizon	113
	Conclusion	114
	References	114

7	Dentofacial Infection	125
	<i>Ashraf Ayoub</i>	
	Introduction	125
	Dentoalveolar abscess	125

Preface

We had the idea of writing a quality textbook on oral and maxillofacial surgery with an international appeal. As editors we have personal links with the Americas, Europe, and Asia, and we were very fortunate to be able to recruit an international cast of authors; by utilizing electronic means of communication, we have been able to assure a high level of coordination and standardization. In this way, we have attempted to cover the full scope of the specialty of oral and maxillofacial surgery. We have incorporated recent technical and biological developments within the specialty. We have all been part of a most exciting development within our surgical field

including both surgical techniques and instrumentation. We have been involved in innovative medical and dental research guiding us in our effort to give optimal care to our patients.

We hope that this textbook will have wide appeal among specialists in oral and maxillofacial surgery and residents in training and will be available as a resource for students, residents, and specialists in allied professions.

This book is dedicated to our teachers and mentors (we stand on the shoulders of giants) as well as the dedication and sacrifices of our wives Karin, Ingrid, and Ann.

Chapter 1

Patient Evaluation

Alan S. Herford and Wayne K. Tanaka

This chapter will cover how to obtain a patient history and carry out a full physical examination. It will cover comorbidities and systemic diseases of relevance to the oral and maxillofacial surgeon in the cardiovascular system (including cardiac disease and hypertension), the pulmonary system (including tobacco use and asthma), and also the endocrine systems, to cover obesity.

Suitable imaging and laboratory studies will also be discussed to arrive at a diagnosis of the patient's medical history, assess anesthetic and surgical risks, and determine whether a procedure would be best carried out in the office or as an inpatient taking into account the medical history.

Summary, 15

The goal of preoperative evaluation is to reduce patient risk and the morbidity of surgery and is based on the premise that it will modify patient care and improve outcome. The preoperative evaluation has several components and should be guided by the patient and surgery being contemplated. It is important to understand that some patients will require an in-depth, thorough examination prior to undergoing surgery, whereas others may benefit from a more focused examination. The type depends on many factors including the age and health of the patient, existing comorbidities, and the type of surgical procedure

planned. Thus, it is important for the clinician to understand how to perform a detailed, in-depth history and physical examination.

The Joint Commission for the Accreditation of Healthcare Organizations (JCAHO) requires that all patients receive a preoperative anesthetic evaluation and the American Society of Anesthesiologists (ASA) has approved Basic Standards for Preoperative Care which outline the minimum requirements for a preoperative evaluation. Preoperative patient assessment is important in order to develop a safe and appropriate surgical and anesthetic plan.¹⁻¹¹ During the preoperative assessment the clinician interviews either the patient or knowledgeable guardian to obtain information. This is followed by a physical examination with special emphasis on the cardiovascular and respiratory systems to help determine risk. Laboratory tests, imaging, and consultations are ordered as deemed necessary based on information obtained during the history and physical examination. Finally, diagnoses are formulated and the treatment options are discussed with the patient followed by obtaining an informed consent.

Obtaining a patient history

The importance of an accurate, detailed history cannot be overemphasized because it provides the framework on which the clinician builds an accurate diagnosis and treatment plan (Fig. 1.1) An inaccurate or incomplete evaluation may lead to a delay in treatment, unnecessary testing, or misdiagnosis.

It is often helpful to review previous medical records. This can provide important information and save time during the interview process. Information such as medications and doses and history of previous surgeries are some examples that can be gleaned from the previous medical records. The clinician may uncover a history of a difficult airway or a history of malignant hyperthermia, and the patient's response to surgical stress and specific anesthetics may be

evaluated. If the patient presents in an altered state, these records can be especially helpful. Preoperative questionnaires and computer-driven programs are becoming more common as a way to gather information and save time. This should help to alert the clinician on areas to focus on but should not be used as an alternative to interviewing the patient.

The clinician must assess the reliability of the person giving the history. Every patient should be asked about their chief complaint (CC). This should be transcribed into the medical record in the patient's own words. The chief complaint assists the clinician in establishing priorities during the history-taking process.

The patient should be asked to describe the history of the present illness (HPI). Information should be gathered regarding onset, intensity, quality, location, duration, radiation, and any exacerbating or relieving factors. Constitutional symptoms that relate to the present illness should also be noted. Examples of pertinent positives and negatives with regard to the chief complaint may include fever, chills, loss of weight, weakness, etc.

The past medical history (PMH) alerts the clinician to any coexisting illnesses that may have an impact on any planned surgeries. Information regarding the severity of an illness should be obtained. For example if a patient reports a history of asthma, the severity and frequency of episodes, previous hospital treatments, and current control should be ascertained. Past surgical history can also help to identify factors that may impact the ability for a patient to undergo a safe surgical procedure. Patients should be asked about medications they are taking as well as any over-the-counter and herbal products. Any allergies to drugs should also be documented, including what type of allergic response a patient may have experienced. A family history (FH) may reveal risk factors for patients as well as the possibility of inherited illnesses such as hemophilia or malignant hyperthermia.

The social history (SH) of a patient should include information regarding their social support system and also any habits such as tobacco, alcohol, or illicit drug use. These habits may adversely affect healing and also increase a patient's risk for undergoing a planned surgical procedure.

A review of systems (ROS) is a comprehensive method of inquiring about a patient's symptoms on an organ system basis. The review of systems may reveal undiagnosed medical conditions unknown to the patient. Concerns raised in the cardiovascular and respiratory systems for example may have importance with regard to a patient undergoing a safe surgical procedure. Patients should also be asked about the presence or recent history of an upper respiratory infection. Symptoms such as shortness of breath, cough, wheezing, stridor, snoring, or sleep apnea can alert the clinician to underlying illness that may increase the risk of morbidity associated with a procedure.

Physical examination

During the physical exam the clinician further reinforces or disproves impressions gained during the history-taking portion. Vital signs are recorded at the beginning of the physical exam. These include blood pressure, pulse rate, respiratory rate, and temperature. Next the patient's general appearance should be noted. It is important when documenting findings to only use commonly used, accepted abbreviations in order to avoid confusion. The physical exam should proceed in a stepwise, systematic manner. Evaluation typically involves inspection, palpation, percussion, and auscultation of the organ system being evaluated. The areas involved typically include the head, eyes, ears, nose, and throat (HEENT) region, in addition to the lungs, abdomen, heart, genitourinary, musculoskeletal, skin, and neurological exam. The detail in which these examinations take place is based on the health of the patient, including any comorbidities, and the type of surgical procedure planned. The examination may be cursory in healthy patients or extensive in patients with coexisting disease. For patients sustaining severe trauma a neurological examination should include a Glasgow Coma Score (Table 1.1). A cranial nerve exam should be performed to uncover any abnormalities (Table 1.2). For patients undergoing facial trauma, the eyes should be evaluated for any afferent pupillary light defects (Fig. 1.2).

Table 1.1 Glasgow coma scale.

EYE RESPONSE (E)

- 4 = Open spontaneously
- 3 = Open to verbal command
- 2 = Open to pain
- 1 = No response

VERBAL RESPONSE (V)

- 5 = Oriented, converses
- 4 = Disoriented, converses
- 3 = Inappropriate responses
- 2 = Incomprehensible
- 1 = No response

MOTOR RESPONSE (M)

- 6 = Obeys verbal command
- 5 = Localizes to pain
- 4 = Withdrawal from pain
- 3 = Decorticate (flex) to pain
- 2 = Decerebrate (extend) to pain
- 1 = No response to pain

NOTE: Scoring exam used to monitor changes in level of consciousness. Score is sum of eye, verbal, and motor responses. Range 3 (worst) to 15 (normal).

It is important to thoroughly assess the airway in patients undergoing anesthesia. This evaluation involves determination of the thyromental distance, the ability to flex the base of the neck and extend the head, and examination of the oral cavity including the dentition and interincisal opening. The Mallampati classification is useful for assessing the tongue size relative to the oral cavity, although by itself the

Table 1.2 Cranial nerves.

Cranial nerve	Function
I. Olfactory	Smell
II. Optic	Visual acuity/fields and fundoscopic examination of each eye
III, IV, VI. Oculomotor, Trochlear, Abducens	Eyelid opening, extraocular movements (IV, superior oblique; VI, lateral rectus; III, all others), direct and consensual pupillary light reflexes
V. Trigeminal (V, ophthalmic; V2, maxillary; V3, mandible)	Corneal reflex, facial sensation, jaw opening, bite strength
VII. Facial	Eyebrow raise, eyelid close, smile, frown, pucker, taste
VIII. Vestibulocochlear	Auditory acuity of each ear, Rinne (air vs bone conduction) and Weber (lateralizing) tests, oculocephalic reflex (doll's eye maneuver), oculovestibular reflex (ear canal caloric stimulation)
IX, X. Glossopharyngeal, Vagus	Palate elevation, swallowing, posterior taste, phonation, gag reflex
XI. Spinal Accessory	Lateral head rotation, neck flexion, shoulder shrug
XII. Hypoglossal	Tongue protrusion and strength on lateral deviation

Fig. 1.2 Afferent pupillary light defect. When the optic nerve is damaged the sensory stimulus sent to the midbrain is reduced. The pupil responds less vigorously and dilates from its prior constricted state (Marcus Gunn pupil).

Mallampati classification has a low positive predictive value in identifying patients who are difficult to intubate (Fig. 1.3).^{12,13} The cervical spine should be assessed and cleared for patients that have undergone significant trauma.

The remainder of the physical examination should proceed in a systematic way. For a complete descrip-

tion of examination techniques the reader is advised to consult textbooks on physical diagnosis.

Comorbidities/systemic diseases

The clinician needs to assess potential risk factors and understand their effect on treatment. Changes in heart rate, rhythm, blood pressure, preload, afterload, and inotropy may occur during surgery and these can have deleterious effects especially in patients with comorbidities. The risks for complications are greatest when caring for patients who are already medically compromised. Many significant untoward events can be prevented by careful preoperative assessment along with attentive intraoperative monitoring and support.¹⁴

Cardiovascular system

Cardiac disease

Cardiac complications following non-cardiac surgery constitute an enormous burden of perioperative morbidity and mortality. More than one million operations annually are complicated by adverse cardiovascular events, such as perioperative myocardial infarction or death from cardiac causes.¹⁵ Common cardiac risk factors include diabetes, hypertension, family history of heart disease, hypercholesterolemia, and obesity. Certain populations of patients, such as the elderly, diabetics, or women, may present with more atypical features.

Methods for evaluating a patient's cardiac risk preoperatively include a careful history, including exercise tolerance, physical examination, and electrocardiogram (EKG). Based on this information, various risk indices, guidelines, and algorithms can assist the clinician in deciding which patients can undergo surgery without further testing and which patients may benefit from further cardiac evaluation or medical therapy prior to surgery. Risk assessment involves evaluating patients' comorbidities and exercise tolerance, as well as the type of procedure to be performed to determine the overall risk of perioperative cardiac complications. Exercise tolerance is a major determinant of cardiac risk and need for further testing. Beta blockade has shown clear benefits in risk reduction whereas revascularization procedures, such as coronary artery bypass grafting, have not been shown useful in reducing non-cardiac surgical risk.^{16–18}

The Goldman Index is a multifactorial index used to assess cardiac risk associated with non-cardiac surgeries. It is based on a study by Goldman *et al.*¹⁹ that prospectively studied 1001 patients. A risk index was formulated based on potential risk factors for cardiac complication and actual complications. For class I patients (0–5 points) only 0.7% had life-threatening complications whereas class IV patients

Class	Direct visualization, patient seated	
Class I	Able to visualize the soft palate, fauces, uvula, anterior and posterior tonsillar pillars	
Class II	Able to visualize the soft palate, fauces, and uvula; the anterior and posterior tonsillar pillars are hidden by the tongue	
Class III	Only the soft palate and base of uvula are visible	
Class IV	Only the soft palate can be seen (no uvula seen)	

Fig. 1.3 Mallampati classification.

(>26 points) experienced life-threatening complications 22% of the time. A previous history of congestive heart failure was the factor most predictive of complications, followed by a myocardial infarction within the previous 6 months. Detsky *et al.*²⁰ included unstable angina and remote myocardial infarction as additional risk factors. They simplified the scoring system into three classes attempting to improve predictive accuracy. In another update of the Goldman

Cardiac Risk Index, Lee *et al.*²¹ studied 4315 patients aged 50 years and older who were undergoing elective, major non-cardiac procedures. Six independent predictors of complications were identified (high-risk type of surgery, history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative serum creatinine >2.0 mg/dl). Cardiac complication rates rose with an increase in

the number of risk factors present. Rates of major cardiac complications with 0, 1, 2, or 3 of these factors were 0.5, 1.3, 4, and 9% respectively, in the derivation cohort and 0.4, 0.9, 7, and 11% respectively, among 1422 patients in the validation cohort.

Angina pectoris can be a symptom of ischemic heart disease. It presents as substernal chest pain that may radiate to the arm, neck, or mandible and represents a reduced delivery of oxygen to the myocardium. It most commonly is the result of coronary heart disease and is classified as stable, unstable, or variant.²² Stable angina pectoris is characterized by no change over 2 months with regards to precipitating factors, frequency, intensity, and duration of attacks. Unstable angina pectoris represents a patient who has experienced worsening of the symptoms recently. Unstable angina pectoris is worrisome because patients are at an increased risk for developing a myocardial infarction.^{23,24} Variant pectoral angina (Prinzmetal's angina) may occur in patients without coronary artery disease and represents vasospasm of the coronary arteries. Patients with angina pectoris should be thoroughly evaluated to determine surgical risk.

The use of vasoconstrictors in local anesthetics in patients with coronary heart disease is controversial in the literature.²⁵ A study by Neves *et al.*²⁶ found no difference in blood pressure, heart rate, or evidence of ischemia in patients treated with or without vasoconstrictor.

Studies estimate the risk of perioperative myocardial infarction to be 0.13% for patients without a history of myocardial infarction and approximately 6% in patients with a history of previous myocardial infarction.^{27,28} Multiple studies have demonstrated an increased incidence of reinfarction if the myocardial infarction was within 6 months of surgery.^{23,29,30}

Congestive heart failure is the single most important risk factor for perioperative cardiac morbidity. Perioperative management includes optimizing fluid management, and maximizing drugs such as inotropes, vasodilators, and antidysrhythmics. Symptoms obtained during the history-taking portion may be worrisome for congestive heart disease. These include findings such as orthopnea and dyspnea. The patient should be questioned about limitation of physical activity such as ability to climb stairs or how far a patient can walk. Signs such as ankle edema, ascites, distended neck vein, and rales on pulmonary auscultation may help to identify congestive heart failure.

Valvular disease can affect the risk of a procedure. Symptoms of valvular disease should be sought, such as angina, syncope, or congestive heart failure from aortic stenosis which would require further evaluation. A history of valvular disease may dictate the need for subacute bacterial endocarditis prophylaxis (Table 1.3). Valvular heart disease presents with a murmur on physical exam. The clinician must determine the severity of the murmur and whether the patient requires preoperative antibiotic prophylaxis to prevent endocarditis.³¹ Aortic stenosis, aortic regurgitation, mitral valve stenosis, mitral valve insufficiency, mitral valve prolapse, and cardiomyopathy are some cardiac conditions which can be detected by cardiac auscultation. Goldman and Caldera recognized aortic stenosis as an independent risk factor for poor outcome increasing the risk for perioperative cardiac death by a factor of 14.³²

Algorithms for preoperative evaluation of cardiac patients undergoing noncardiac surgery are useful in guiding the need for further testing and evaluation. These algorithms are based on the available evidence and expert opinion that integrates clinical history, surgery-specific risk, and exercise tolerance. Implementation of American College of Cardiology / American Heart Association (ACC / AHA) guidelines for cardiac risk assessment prior to non-cardiac surgery reduces preoperative resource utilization, improves medical treatment, and preserves a low rate of perioperative cardiac complications.^{33,34} Studies have shown perioperative cardiac morbidity is greatly reduced by perioperative β -adrenergic blockade administration.^{35,36} The American College of Physician Guidelines uses the Detsky modification of the cardiac risk index.^{20,37} Patients that are class II or III are considered high risk. For patients that are classified as class I, other clinical factors can be used to further stratify risk. The Guidelines suggest that there is insufficient evidence to recommend diagnostic testing for non-vascular surgery patients.

In patients for whom further work-up is deemed necessary, this may include cardiovascular tests such as EKG, non-invasive cardiovascular tests such as an exercise EKG or pharmacologic testing in patients who are unable to exercise. The exercise EKG is the most cost-effective and least invasive method for detecting ischemia, with a sensitivity of 70–80% and

Table 1.3 AHA SBE prophylaxis regimens.

	Adult	Child

specificity of 60–75% for identifying coronary artery disease. Pharmacologic stress thallium imaging is useful in those patients unable to exercise. Dipyridamole or adenosine is administered as a coronary vasodilator to assess flow heterogeneity. A redistribution defect is predictive of perioperative cardiac events. Dopamine can also be used to increase myocardial oxygen demand, by increasing the heart rate and blood pressure. Stress echocardiography is another preoperative test that can reveal regional wall motion abnormalities which represent areas at risk for myocardial ischemia. Echocardiography can assess cardiac ejection fraction and also provide information regarding valvular function. Coronary angiography provides information regarding the coronary anatomy. Unlike exercise or pharmacologic stress tests, coronary angiography provides anatomic, not functional, information.

Hypertension

Hypertension is a common disease which can increase perioperative cardiac risk. Hypertension has been associated with an increase in the incidence of silent myocardial ischemia and infarction.³⁸ The Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure recently revised their definition.³⁹ Hypertensive patients with left ventricular hypertrophy are at a higher perioperative cardiac risk than non-hypertensive patients.⁴⁰

Controversy exists regarding whether to delay a surgical procedure in a patient with untreated or poorly controlled hypertension. Aggressive treatment of high blood pressure does diminish long-term risk. A study often quoted as the basis for delaying surgery for patients with a diastolic blood pressure greater than 110 mmHg actually demonstrated no major morbidity in that group of patients.³² Other authors have found little association between blood pressures less than 180 mmHg systolic or 110 mmHg diastolic and postoperative outcomes. Patients with severe hypertension are more prone to perioperative myocardial ischemia, ventricular dysrhythmias, and lability in blood pressure. For patients with blood pressures greater than 180/110 mmHg there is no absolute evidence that postponing surgery will decrease the cardiac risk.⁴¹ For patients without end-organ changes, such as renal insufficiency or left ventricular hypertrophy, it may be appropriate to proceed with surgery. However patients with a markedly elevated blood pressure and new onset of a headache should have surgery delayed for further medical treatment. Patients with hypertension may have a contracted intravascular volume and therefore have an increased susceptibility to vasodilator effects of commonly used sedative and anesthetic agents. For elective surgery it is best to have the patient's blood pressure optimized prior to surgery.

Risk factors for hypertension include smoking, hypercholesterolemia, increasing age, family history of cardiovascular disease, and diabetes. Untreated hypertension commonly causes coronary heart disease, cardiomegaly, congestive heart failure, and end-organ damage. When evaluating a patient with hypertension, it is important to determine the presence of end-organ damage (heart, lung, and cerebrovascular systems). An elevated systolic blood pressure may be a better predictor of postoperative myocardial ischemia than elevated diastolic blood pressure.³⁹

Pulmonary system

Pulmonary complications are a major cause of morbidity for patients undergoing a surgical procedure. They occur more frequently than cardiac complications with an incidence of 5–10% in those having major non-cardiac surgeries.^{42,43} Perioperative pulmonary complications include atelectasis, pneumonia, bronchitis, bronchospasm, hypoxemia, and respiratory complications.⁴⁴ Both the site and type of surgery are the strongest predictors of complications. With regards to the surgical site, thoracic surgery is associated with the highest risk for perioperative pulmonary complications, whereas major head and neck surgery is associated with a 24–47% risk of pulmonary complications.^{45,46} A decrease in postoperative vital capacity and functional residual capacity contributes to hypoxemia and atelectasis.⁴⁷ General anesthesia also results in mechanical changes such as a decrease in the functional residual capacity as well as an altered diaphragmatic motion. This can lead to a mismatch between ventilation and perfusion creating shunting and dead space ventilation. The functional residual capacity may take up to 2 weeks to return to baseline.⁴⁸ A general anesthetic can also cause inhibition of mucociliary clearance, increased alveolar capillary permeability, inhibition of surfactant release, and increased sensitivity of the pulmonary vasculature to neurohormonal mediators. The duration of anesthesia has been shown to be a risk factor for postoperative pulmonary complications, with morbidity rates increasing after 2–3 hours.⁴⁹

For patients with an upper respiratory illness, surgery should be delayed if possible for at least 2 weeks after resolution of the illness. A recent study found a 10% incidence of severe complications, respiratory as well as cardiac arrest, pneumonia, and prolonged intubation due to increased sputum.⁵⁰

During the presurgical evaluation, the clinician should obtain information about exercise tolerance, chronic cough, or unexplained dyspnea. On physical exam, findings of rhonchi, wheezing, decreased breath sounds, dullness to percussion, and a prolonged expiratory phase are important. Preoperative pulmonary function tests are usually reserved for patients undergoing lung resection or those undergoing major surgery who have unexplained pulmonary

signs and symptoms after a history and physical examination.

Tobacco

Tobacco is an important risk factor. Even among smokers without chronic lung disease, smoking is known to increase carboxyhemoglobin levels, decrease ciliary function, and increase sputum production. Nicotine also stimulates the cardiovascular system. Discontinuing smoking for 2 days can decrease carboxyhemoglobin levels, abolish nicotine effects, and improve mucus clearance. However, a study by Warner showed that smoking cessation for at least 8 weeks was necessary to reduce the rate of postoperative pulmonary complications.⁵¹ Patients who smoke often show an increase in airway reactivity under general anesthesia. Administration of a bronchodilator such as fluticasone preoperatively may be beneficial in this group of patients.⁵²

Asthma

Asthma causes episodic narrowing of the small airways, which produces wheezing and dyspnea. Patients should be questioned regarding precipitating factors, frequency and severity of attacks, medications used, and current status. Frequent use of bronchodilators, hospitalizations for asthma, and the requirement for systemic steroids are all indicators of the severity of the disease. Airway hyper-reactivity may persist for several weeks after an episode of asthma.⁵³ Patients may require xanthine-derived bronchodilators, such as theophylline, and corticosteroids. Cromolyn sodium is useful for protecting against acute attacks but is ineffective once broncho-

spasm occurs. Sympathomimetic amines in aerosol form such as epinephrine or metaproterenol can be administered if wheezing begins. Clinicians should be aware of the role of anxiety in initiating bronchospasm and also the potential adrenal suppression in patients receiving corticosteroid therapy. Elective therapy should be delayed if a respiratory tract infection or wheezing is present. In addition to bronchodilators, perioperative steroids may be beneficial as prophylaxis for severe asthmatics. The possibility of adrenal insufficiency is also a concern for patients who have received extended treatment with steroids and should be administered "stress doses" of steroids perioperatively. The risks of complications are low for asthmatics treated with short-term steroids undergoing surgery.⁵⁴ There is no association with impaired wound healing or infections. It is recommended for patients using inhaled steroids that these be regularly administered starting at least 48 hours prior to surgery for optimal effectiveness.⁵⁵

Endocrine system

Endocrine disorders can affect the course of anesthesia and should be evaluated preoperatively (Table 1.4). A decrease in adrenal cortical activity such as seen in Addison's disease, may lead to a decreased production and availability of cortisol and aldosterone thus altering cardiovascular stability. Patients who are taking glucocorticosteroids may have suppression of the pituitary gland and may require supplementation of cortisol (rule of twos). In patients on long-term corticosteroids, the clinician should have a high index of suspicion for adrenal cortical suppression and Cushing's syndrome. Classic symptoms found in Cushing's syndrome include

Table 1.4 Clinical manifestations of endocrine diseases.

	Diabetes mellitus	Pheochromocytoma	Addison's disease	Hyperthyroidism	Hypothyroidism	Hyperparathyroidism
General	Polydipsia/polyuria	Heat intolerance, palpitations, intermittent hypertension, sweating	Fatigue, sweating	Heat intolerance, warm, moist skin	Cold intolerance	Polydipsia
Cardiovascular	Cerebrovascular disease	Tachycardia, bounding pulse	Sudden drops in blood pressure	Tachycardia, atrial fibrillation, congestive heart failure	Bradycardia, cardiomegaly,	Hypertension, heart block
Neurologic	Blurred vision, retinopathy	Headaches, diaphoresis	Dizziness, headache	Nervousness, tremor, hyperactive reflexes	Slow mental function, hyporeflexia	Weakness, lethargy, headache, insomnia
Gastrointestinal	Weight loss	Weight loss, abdominal pain	Weight loss, diarrhea	Diarrhea	Delayed gastric emptying	Anorexia, nausea, vomiting, constipation
Musculoskeletal	Charcot joints	Signs of poor perfusion	Muscle weakness, joint and muscle pain	Muscle weakness, bone resorption	Large tongue, amyloidosis	Bone pains, arthritis, pathologic fractures
Renal	Kidney disease	Urinary retention	Urinary loss of sodium	Chronic renal failure	Impaired free water clearance	Polyuria, hematuria

moon facies, striations of the skin, trunk obesity, hypertension, easy bruisability, and hypovolemia. These patients should have any fluid and electrolyte abnormalities corrected preoperatively.

Patients with a pheochromocytoma may present with overproduction of epinephrine and norepinephrine in the adrenal medulla which can lead to hypertension and tachycardia intraoperatively. The classic findings for pheochromocytoma include intermittent hypertension, headache, diaphoresis, and tachycardia. In patients with other endocrine tumors, a pheochromocytoma should be ruled out as part of a multiple endocrine neoplasia (MEN) syndrome.

Thyroid and parathyroid disease have clinical manifestations that are important to evaluate preoperatively. Disorders of the thyroid can present as hypothyroidism or hyperthyroidism. The presurgical evaluation should focus on the signs and symptoms of hyperthyroidism and hypothyroidism. Thyroid function tests including thyroid stimulating hormone (TSH), triiodothyronine (T3), and thyroxine (T4) are used to assess for disorders of the thyroid. Patients with hypothyroidism may exhibit cold intolerance, myxedema, fatigue, and/or depression. Severe hypothyroidism can lead to coma, cardiovascular collapse, and heart failure, and surgery should be postponed until it is corrected. Hyperthyroidism, such as seen in Grave's disease, presents with symptoms including hyperexcitability, weight loss, hypertension, and tachycardia. Thyroid storm can occur during anesthesia. Medications such as propylthiouracil or methimazole may be helpful preoperatively to reduce thyroxine secretion. Beta-blockers may be useful to stabilize the adrenergic activity during surgery. Large goiters may impact the patency of the airway and make intubation more difficult. Patients with hyperparathyroidism often have hypercalcemia and the serum calcium level should be determined preoperatively.

The pituitary gland has control of many glands and organs. Increased production of pituitary hormones can lead to secondary hyperthyroidism, secondary Cushing's syndrome, and acromegaly.

Diabetes mellitus is the most common endocrinopathy and has both acute and chronic disease manifestations. The disease process causes impairment of normal blood flow and subsequent end-organ damage. Type 1 diabetes is characterized by insulin dependency and typically occurs at a young age, whereas type 2 diabetes is often non-insulin dependent and occurs later in life. Preoperative assessment of patients with diabetes includes determining their degree of blood sugar control and evaluation of any end-organ damage. Perioperative complications increase with poorly controlled diabetes with end-organ damage. Diabetics have an increased risk of coronary artery disease, perioperative myocardial infarction, hypertension, and congestive heart failure. They are also at an increased risk for cerebral vascular, peripheral vascular, and renal vascular disease.

Myocardial infarction or ischemia may be "silent" if diabetic autonomic neuropathy is present. Diabetes accelerates the progression of atherosclerosis leading to a higher incidence of coronary artery disease than in non-diabetics. There is also a higher incidence of silent myocardial infarction in this group of patients. Eagle *et al.*³⁴ demonstrated that diabetes is an independent risk factor for perioperative cardiac morbidity. An EKG should be obtained to examine for the presence of Q waves. Laboratory assessments for diabetics include a blood sugar and HbA1c. A blood glucose level gives a value at one point in time whereas the glycosylated fraction of adult hemoglobin (HbA1c) gives a better assessment of control over the previous 2 months. Perioperative concerns with diabetic patients include poor healing with possible infection and diabetic ketoacidosis. Hypoglycemia should be avoided in order to prevent central nervous system damage. Managing surgical patients with diabetes must take into account the type of diabetes, how well the patient controls their blood sugar, and the stress associated with the surgical procedure.

Obesity

A patient is considered obese when their body weight is 20% or more above ideal weight. Obesity can be measured by the body mass index (BMI) which is derived by dividing the weight in kilograms by the height in meters squared ($BMI = Wt/ht^2$).

A BMI greater than 30 suggests increased morbidity due to stroke, heart disease and diabetes.⁵⁶ At a minimum, these conditions indicate the need for close evaluation of the patient's airway and cardiac and pulmonary status.⁵⁷ Even with an adequate airway, ventilation may be difficult because of the patient's size and a tendency toward hypoxemia. There may also be significant cardiovascular changes.

On the other hand, the clinician should not dismiss a low BMI, especially with evidence suggesting an eating disorder. Nutritional deficiency may be present along with significant cardiac changes, fluid and electrolyte imbalances, delayed gastric emptying, and severe endocrine abnormalities.⁵⁸

Other organ systems

Disease affecting the renal system has important implications for fluid and electrolyte management, as well as the metabolism of certain drugs. Liver disease is associated with altered protein binding and volume distribution of drugs, as well as coagulation disorders.

Patients should be questioned regarding bleeding problems. This includes questions regarding bruising, bleeding, and the use of medications that influence platelet function such as aspirin, other non-steroidal anti-inflammatory drugs, and anticoagulants. Medications such as acetyl-salicylic acid and other non-selective non-steroidal anti-inflamma-

Table 1.5 Clotting indices.

Measurement	Normal result	Comments
Prothrombin time (PT)	11–15 s	Measures intrinsic and common pathways (Factors I, II, V, VII, and X)
Activated partial thromboplastin time (aPTT)	20–35 s	Measures extrinsic and common pathways (Factors I, II, V, VIII, IX, X, XI, and XII)
Bleeding time	2–7 minutes	Tests platelet and vascular phases (independent of coagulation cascade)
Thrombin time	6.3–11.1 s	Measures ability to form initial clot from fibrinogen
International normalized ratio (INR)	1.0	(PT patient/PT control) × international sensitivity index (ISI)
Fibrinogen	200–400 mg/dl	Factor I

tory analgesics can inhibit platelet function. Liver disease may decrease the amount of clotting factors. Inherited disorders such as von Willebrand's disease and hemophilia A and B may require administration of various factors preoperatively to minimize bleeding risk.⁵⁹ Reduced ristocetin cofactor levels are often seen in patients with von Willebrand's disease.⁶⁰

Screening tests for bleeding disorders include prothrombin time (PT) or international normalized ratio (INR) to assess the extrinsic and final common pathway and activated partial thromboplastin time (PTT) to test the intrinsic and final common pathways (Table 1.5). Platelet counts may be helpful in patients with thrombocytopenia. Bleeding times measure qualitative platelet function. They are used less and may be unreliable.

Patients with transient ischemic attacks (TIAs) or stroke should undergo a thorough evaluation. Patients who have had unstable TIAs or a stroke within the previous 6 months should have their surgery delayed if possible. Surgery can lead to a hypercoagulable state which may exacerbate cerebral arterial disease. Questioning should include the degree of compliance with medical therapy.

Controversy exists regarding the management of patients on anticoagulation therapy. Some clinicians prefer to admit a patient to the hospital and begin therapy with heparin. This can then be stopped immediately prior to surgery followed by restarting the heparin after the surgical procedure and while beginning oral therapy with warfarin. Low-molecular-weight heparin can be considered as a way to bridge anticoagulation during the interruption of warfarin for high bleeding-risk procedures.⁶¹ A study by Ferrieri *et al.*⁶² noted a low 1.96% risk of bleeding complications in patients undergoing oral surgical procedures with an INR ≤ 5.5 who did not stop their oral anticoagulant therapy. Other authors have found that it is not necessary to reduce oral anticoagulant therapy.^{63–65}

Disorders of the musculoskeletal system have been associated with an increased risk of malignant hyperthermia. Osteoarthritis may result in difficulty exposing the glottic opening during intubation. Rheumatoid

arthritis is a multisystem disease and a thorough review of systems should be performed. These patients may have restrictive lung disease, temporomandibular joint manifestations with restricted opening and hypoplastic jaw, pleural effusions, pericarditis, and anemia. Epilepsy is a common neurological disorder. Patients should be questioned on frequency, duration, and type of seizures they experience. Risks of pulmonary aspiration and respiratory insufficiency during seizure episodes should be taken into account.

Imaging

A patient's presentation will dictate which films are required. Radiographs such as plain films, cone beam, fanning computed tomography (CT), nuclear scans, and arteriography are helpful in various circumstances. The risks associated with these studies should be weighed against the added benefit from them.

Laboratory studies

Many institutions have preadmission screening test algorithms based on factors such as age of the patient (Table 1.6). Preoperative laboratory tests should be ordered based on defined indications such as positive findings on a history and physical exam. A thorough history and physical examination can be used to identify those medical conditions that might affect perioperative management and direct further laboratory testing. A study by Golub *et al.*⁶⁶ reviewed the records of 325 patients who had undergone preadmission testing prior to surgery. Of these 272 (84%) had at least one abnormal screening test, while only 28 surgeries were canceled or delayed. Only three patients potentially benefited from preadmission testing, including a new diagnosis of diabetes in one and non-specific EKG changes in two. Another study by Narr *et al.*⁶⁷ demonstrated minimal benefits from routine testing and proposed that routine laboratory screening tests were not required in healthy patients.

Table 1.6 Sample preadmission screening test algorithm. (EBL, estimated blood loss; HTN, hypertension; IVDA, intravenous drug abuse; LMP, last menstrual period; ABG, arterial blood gases; CBC, complete blood count; PT, prothrombin time; PTT, partial thromboplastin time; LFTs, liver function tests; CXR, chest X-ray; EKG, electrocardiogram; HCG, human chorionic gonadotropin; UA, urinalysis; PFTs, pulmonary function tests; T/S, type and screen.)

CIRCLE APPROPRIATE LABS TO ORDER												
Preoperative condition	ABGs	CBC	PT/PTT	Lutes	BUN/Creat	Blood/Glucose or Accucheck	LFT	CXR	EKG	Hcg preg/UA	PFTs	T/S
Possible EBL >500 ml		X										X
Neonates		X										
Age: >40 yr									X			
Age: >75 yr		X				X			X			
Cardiovascular disease/ chronic HTN		X			X			X	X			
Use of diuretics, digoxin				X*	X				X			
Severe pulmonary disease/ prethoracotomy	X	X						X	X		X	
Malignancy/radiation/ chemotherapy		X,plt		X	X							
Hepatic disease		X,plt					X					
Chronic alcoholism		X,plt		X	X		X		X			
Renal disease (dialysis)		X		X*	X*			-/+	-/+			
Bleeding disorder/ anticoagulant therapy		X,plt*	X*									
Diabetes				-/+	X	X*			>30 yr			
Possible pregnancy/ gyn surgery										X*		
IVDA									>30 yr			

Note: Not all diseases are included. Therefore, the physician should use own judgment regarding patients having diseases that are not listed.

In patients with stable medical conditions, labs and EKGs within the last 3 months, and CXR within the last year, will be acceptable.

X Items should be done within 72 hours of surgery.

* Urine pregnancy test if LMP >21 days with possibility of pregnancy or menstruating females <18 years of age, all women undergoing tubal ligation and all women having a hysterectomy who are in their reproductive years or who are experiencing the first year of menopause.

Table 1.7 American Society of Anesthesiologists physical status classification.

Status	Disease state
ASA class 1	No organic, physiologic, biochemical, or psychiatric disturbance
ASA class 2	Mild to moderate systemic disturbance that may not be related to the reason for surgery
ASA class 3	Severe systemic disturbance that may or may not be related to the reason for surgery
ASA class 4	Severe systemic disturbance that is life threatening with or without surgery
ASA class 5	Moribund patient who has little chance of survival but is submitted to surgery as a last resort (resuscitative effort)
Emergency operation (E)	Any patient in whom an emergency operation is required

In a follow-up study a cohort of patients was followed who had no preoperative testing and was found to include no deaths or major morbidity.⁶⁸ By combining information from the history, physical examination, exercise tolerance, and stress of a proposed surgical procedure, inappropriate testing can be reduced, whereas, more importantly, appropriate screening tests will be performed.

Arriving at a diagnosis

During the history-taking portion of the preoperative evaluation the surgeon is developing a list of possible diagnoses. By examining the patient he or she then proceeds to further narrow the possible diagnoses and solidify clinical impressions developed during the history. Laboratory data and imaging may further clarify the diagnosis or diagnoses. Once the clinician has obtained enough information a treatment plan can be developed. The patient is informed of the risks, alternatives, and possible benefits to a potential procedure.

Assessing anesthetic/surgical risk

Once the clinician has gathered information by interviewing and examining the patient, he or she can classify them according to the American Society of Anesthesiologists (ASA) Classification of Physical Status (Table 1.7). Patients with a lower ASA classification represent a lower surgical risk than do patients with severe systemic disease. This system is commonly used and is helpful in identifying risk factors so that modifications in the treatment plan can be undertaken. The surgical procedure influences the scope of preoperative evaluation required by determining the potential range of physiologic flux during the perioperative period. The AHA/ACC guidelines describe risk stratification for non-cardiac surgery.⁶⁹ These can be divided into low, intermediate, and high with a reported risk of cardiac death and non-fatal myocardial infarction of <1, <5, and >5% respectively. Head and neck surgeries are considered intermediate-risk procedures. Examples of low-risk procedures would be cataract surgery and superficial procedures, whereas high-risk procedures would be surgeries such as emergency major operation or anticipated prolonged surgical procedures associated with large fluid shifts and/or blood loss.

Office vs inpatient

Once the clinician has gathered pertinent information during the preoperative work-up, he must decide where best to perform the surgical procedure.

Safety continues to be the guiding factor in deciding where various types of procedures should be per-

formed. Options available include office surgery, ambulatory surgery centers, and traditional hospital-based locations. Many variables are considered when deciding on whether to perform a surgery in the office or perform the surgery elsewhere.

Oral and maxillofacial surgeons routinely perform a large number and variety of procedures in the office setting. There the surgeon can perform the procedures under local anesthetic, intravenous (IV) sedation or general anesthetic. Oral and maxillofacial surgeons have developed an excellent track record with a long history of patient safety. Perrott *et al.* looked at outcomes of office-based ambulatory anesthesia by oral and maxillofacial surgeons.⁷⁰ The study involved 34191 patients, of whom 71.9% received deep sedation or general anesthesia, 15.5% received conscious sedation, and 12.6% received local anesthetic. The complication rate was 1.3% and almost all complications were minor and self-limiting. Only two patients had complications requiring hospitalization. In fact, oral and maxillofacial surgeons have been performing surgeries in an office setting much longer than other specialties. Their training and ability qualifies them to manage a patient's airway as well as any emergencies, thus minimizing surgical risk.

The type of procedure is an important determinant of where the surgery should be performed. For local bone graft harvest, the invasiveness of the surgery is similar to surgically removing impacted third molar teeth, and the risk to patients is low. Harvesting bone from the posterior iliac crest and cranium, on the other hand, is more invasive, and although the risk of major complications is low, the risk is higher than for local graft harvest. These complications include bleeding from the surgical site and postoperative infection. It is important when performing these types of procedures in the office or ambulatory surgery center to avoid compromising the sterility of the procedure.

Patient factors should also be an important part of the decision on where to perform the procedure. Patients with poorly controlled medical conditions such as morbid obesity or poorly controlled hypertension should be carefully evaluated, and appropriate preoperative testing should be performed to determine their surgical risk. Patient factors such as increased age, an operating time longer than 120 minutes, cardiac diagnoses, peripheral vascular disease, cerebrovascular disease, malignancy, and immunodeficiency can place patients at higher risk for immediate hospital admission.⁷¹

Advantages of performing surgery in a hospital setting include the addition of another health care provider to administer anesthetic during the surgical procedure. Imaging techniques such as ultrasonography, CT, and chest radiographs are readily available as are blood chemistries to rapidly diagnose and treat complications. Also procedures such as interventional radiology, for such things as embolization, are available. Ultimately the decision on where to perform a

surgery depends on both the surgeon and informed patient considering the type and length of the procedure, patient health factors, and safety.

Summary

The process of preoperative evaluation is essential in assessing the medical condition of patients, evaluating their overall health status, determining risk factors, and educating them. The goal of preoperative evaluation is to reduce patient risk and the morbidity of surgery.

Chapter 2

Radiographic Imaging in Oral and Maxillofacial Surgery

Arne Petersson

This chapter covers current imaging modalities for the maxillofacial region. Although plain film radiography is covered, the majority of the chapter is devoted to the use of computed tomography (both conventional and cone beam CT), magnetic resonance imaging, and positron emission tomography (PET). The most appropriate imaging technique for impacted teeth, inflammatory lesions, cysts and benign tumors, and malignant tumors is discussed.

Introduction, 17

Computed tomography (CT), 17

Implant treatment, 25

Introduction

The most common radiographic examinations of oral and maxillofacial surgery patients are intraoral and panoramic radiographs. However, today computed tomography (CT) and magnetic resonance imaging (MRI) are common examinations in imaging of many different conditions. A useful investigation is one in which the result – positive or negative – will alter management or add confidence to the clinician's diagnosis.¹ It is sometimes difficult to decide which examination technique(s) should be used and it is often helpful to discuss this with a specialist in oral and maxillofacial radiology before deciding the investigation. The radiological examination must be based on the clinical information and the specific questions that should be answered. It is also important to try to minimize the radiation dose to the patient and especially CT can potentially give very

high absorbed doses to the patient. The trend today is to use a low-dose technique for CT, but this can be at the expense of the image quality and its use depends on the clinical problem.

Computed tomography (CT)

CT is a digital technique providing images of thin slices of the patient with a variable thickness. The slice thickness can be less than 1 mm by use of very small X-ray detectors and a fan-shaped X-ray beam transmitted through the patient. By simultaneously scanning several slices of the body (multislice CT), the scan time can be reduced significantly and the smallest details can be imaged within short scan times. Multislice CT enables a wide range of clinical applications and, through the use of computer software, three-dimensional (3D) images can be produced. Images can be viewed in the axial, coronal, or sagittal planes depending on the diagnostic task. This is referred to as multiplanar reformatted (MPR) imaging. Images can also be viewed in any other plane decided by the operator. CT has the advantage over other radiographic techniques that it eliminates superimposition of images of structures outside the area of interest. It has an inherent high-contrast resolution and differences between tissues that differ in physical density by less than 1% can be distinguished. For image display, each pixel is assigned a CT number (Hounsfield units – HU) representing density. The density of air is defined as –1000HU, water as 0HU and bone tissue has more than +400HU. To allow the observer to interpret the image, only a limited number of HU are displayed. A clinically useful gray scale is achieved by setting the window level and window width on the computer console to a suitable range of HU, depending on the tissue being studied. The term 'window level' represents the central HU of all the numbers within the window width. The window width covers the HU of all the tissues of interest and these are displayed as various shades of gray.

Cone-beam computed tomography (cone-beam CT)

This technique has been commercially available for the last few years. Cone-beam CT is based on volumetric tomography, in contrast to conventional fan-beam CT where slices are scanned. From this volume slices can be reconstructed in various planes. One advantage with cone-beam CT compared to conventional CT is the lower radiation dose. The radiation dose is reduced by up to 98% compared with conventional CT² and is comparable to 3–28 average panoramic radiographs.³ The dose varies substantially, however, depending on the device, imaging field and selected technique factors.³ The scan time is relatively short (around 20s) and the resolution is high (i.e. 0.125mm in Accuitomo®, Morita). The software is usually adapted to maxillofacial imaging and is real-time interactive, for example for implant planning. In both cone-beam CT and conventional CT artifacts are produced by metal objects and it is important to try to avoid exposing metal fillings and crowns.

Magnetic resonance imaging (MRI)

MRI does not use ionizing radiation. There are, however, some contraindications as the presence of ferromagnetic metals is a potential hazard. Patients with metallic foreign objects, pacemakers, and metal clips must not be examined. Pregnancy is a relative contraindication. The advantage of MRI is that it offers the best resolution of tissues of low inherent contrast and it has an excellent soft tissue contrast resolution. Disadvantages are relatively long imaging times and patients suffering from claustrophobia cannot be examined. MRI physics is very complicated and an understanding of the basic concepts is important in order to manipulate the scan parameters to improve the quality of the images. All imaging should be discussed with the radiology department to get optimal information.

Impacted teeth

A preoperative examination of an impacted tooth usually consists of two intraoral radiographs exposed at different angles (Fig. 2.1) or a panoramic radiograph. Using intraoral films in three different projections gave an insight into the true anatomy of third molars when the radiographic appearance was compared to the clinical observation.⁴ Intraoral and panoramic radiographs are usually sufficient to show the relationship between the roots of the third molar and the mandibular canal. However, narrowing of the canal, increased radiolucency (“dark band”) and interruption of the radiopaque border of the mandibular canal can justify a CT examination.^{5–7} Recently, cone-beam CT has been shown to have a high diagnostic accuracy in predicting neurovascular bundle

exposure during extraction of impacted mandibular third molars.⁸ Fig. 2.1 shows an example of an impacted mandibular third molar with a complicated root anatomy examined with cone-beam CT.

CT is also valuable when examining impacted teeth in other regions.⁹ Cone-beam CT has been shown to be indicated for localization of impacted maxillary canines¹⁰ and conventional CT demonstrated root resorption better of the adjacent incisors compared to conventional radiography.^{11,12} Fig. 2.2 shows a cone-beam CT examination of a non-erupted maxillary canine causing resorption of the root of the lateral incisor.

Pathological conditions – inflammatory lesions, cysts, benign and malignant tumors

The aims of the radiographic examination are to give information that leads to the most probable diagnosis and to the best treatment. The examination must cover the whole pathological area in at least two dimensions. A combination of different radiographic techniques can lead to a more certain diagnosis, but it should always be kept in mind that the treatment also must be affected positively by the extended examinations in order to be justified. There are some radiological signs that always must be looked for when interpreting radiographs of pathological conditions, such as:

- location and size;
- periphery and shape;
- internal structures;
- effects on surrounding structures.

Inflammatory lesions

There are several lesions that present as a radiolucent area in the jaws. Inflammatory lesions located in the periapical area are by far the most common changes. It is not possible to differentiate radiologically between a radicular cyst and apical periodontitis. Radicular cysts tend to be larger than periapical granulomas, but a large variation in size has been shown for both types of lesions.¹³ This is not a diagnostic problem for small periapical radiolucencies as endodontic treatment has a high success rate¹⁴ and the prevalence of true cystic lesions is low.¹⁵ At follow-up after endodontic treatment and periapical surgery it is important to standardize the radiographic examination regarding projection and density/contrast of the image to be able to compare different examinations. An example is given in Fig. 2.3 where the projection was changed between the two radiographs taken on the same occasion and it appears that the size of the periapical bone destruction has changed.

Fig. 2.1 Impacted lower third molar in a mesioangular position. (a) Periapical radiograph taken with +10° vertical angulation of the X-ray tube. Two mesial roots (one straight and one curved) and one distal root are seen. (b) Periapical radiograph taken with -10° vertical angulation of the X-ray tube. The mandibular canal seems to be buccal to the curved root. (c) Cone-beam CT with 1 mm thick sections. Upper left image is a cross-section of the mandible through the roots. The mandibular canal is seen below the mesial roots, lingual to the buccal root and buccal to the lingual root. Upper right image is a sagittal view of the buccal part of the tooth and the straight mesio-buccal root is shown. Lower section shows an axial view of the tooth, which is situated close to the lingual compact bone. (d) Same as (c), but the section is lingually placed. The curved mesio-lingual root is shown in the sagittal view.

Fig. 2.2 Cone-beam CT examination of a non-erupted maxillary canine causing resorption of the root of the lateral incisor. The crown of the canine is situated palatal to the root of the incisor. (a) Upper left, sagittal view. Upper right, cross-section of the jaw. Lower, axial view. (b) Same as (a), but the 1 mm thick section is placed more palatal in the sagittal section. The root tip of the canine is curved mesially.

Fig. 2.3 Evaluation of healing after apical surgery of the upper left canine. Radiographs in (a) and (b) are taken at the same occasion, but with different projections. The apical bone destruction has a different appearance depending on the change of projection

Cone-beam CT should be considered when no detectable pathology is found in periapical radiographs and clinical tests indicate pathology, as more periapical lesions are found with cone-beam CT.^{16,17} This is especially important in patients with chronic maxillary sinusitis, as a dental cause was found in 40% of patients with chronic maxillary sinusitis.¹⁸

Radiographs of the paranasal sinuses are not indicated routinely when sinusitis is suspected. Panoramic radiography should not be used for the detection of small osteolytic lesions in the maxillary sinus¹⁹ and soft tissue changes can be difficult to detect in panoramic radiographs depending on whether the surrounding structures are projected into the maxillary sinuses. CT is more rewarding than conventional radiography in the examination of the paranasal sinuses.²⁰ Low-dose high-resolution CT is recommended,²¹ when medical treatment has failed, when complications arise or if malignancy is suspected.¹ Fig. 2.4 shows a case of chronic maxillary sinusitis examined with panoramic radiography and low-dose CT.

Osteomyelitis, osteonecrosis, and osteoradionecrosis are conditions that have similarities in their radiographic appearance. Osteomyelitis is an inflammatory condition of bone that involves the medullary cavity and has a tendency to progress along this space and involve the adjacent cortex, periosteum and soft tissue.²² Osteonecrosis of the jaws is a condition that shows as a painful bone exposure, often after bisphosphonate treatment.²³ Another form of osteonecrosis is the feared complication of radiation therapy (osteoradionecrosis).

In a review article of diagnostic modalities of skeletal infections, plain films are recommended as the first step in the imaging assessment of osteomyelitis, but the sensitivity of plain films is low.²⁴ CT provides more diagnostic information than plain films about bone changes and also shows soft tissue changes. Bone scintigraphy has a higher sensitivity than radi-

Fig. 2.4 A patient with chronic maxillary sinusitis. Panoramic radiography (a) and low-dose CT (b, c) were performed. (a) Panoramic radiograph showing root fragments of the upper left third molar with periapical bone destruction. The maxillary sinuses are difficult to evaluate. (b) Axial CT showing complete radiopacification of the left maxillary sinus. The bony walls are slightly sclerotic. (c) Coronal reconstruction showing the same picture as (b).

ography and changes may be visualized in early phases.²⁴ However, MRI has also proven to have a high sensitivity in the early detection of osteomyelitis.²⁴ In the jaws osteomyelitis is more common in the mandible and can be difficult to diagnose. Radiographically it is most important to confirm the clinical suspicion and to localize the condition. It is also important to examine its extent and to assess the response after treatment. In the mandible the extent of inflammation was better appreciated with CT than with conventional radiography, especially in cases with diffuse changes such as cortical plate disruption and periosteal reaction.²⁵ Fig. 2.5 shows a child with chronic osteomyelitis illustrating the superiority of CT over panoramic radiography in showing bony involvement. Four radiographic patterns have been identified from computed tomograms: the most common was a mixed pattern with osteosclerosis and osteolysis, the second most common was sclerotic pattern, the third most common was a lytic pattern, and finally the least common was sequestration with or without other bony changes.²⁵ Periosteal reaction was found in 40% in cases of osteomyelitis, especially in younger patients.²⁶ Cone-beam CT offers a good alternative to conventional CT in examining osteomyelitis of the mandible.²² MRI using a combination of T1- (low-intermediate signal) and T2-weighted (high-intermediate signal) images showed larger areas of abnormality than plain radiography or CT.²⁷ A combination of T1-weighted and so-called STIR

Fig. 2.5 13-year old girl with pain and swelling of the left mandible. The diagnosis was chronic osteomyelitis. (a) Panoramic radiograph showing sclerosis, thick periosteal reaction, and destruction of the cortical delineation of the mandibular canal and tooth bud of the third molar on the left side. (b) CT showing the expansion of the mandible and bone destructions more clearly than panoramic radiography. (c) Bone scan using ^{99m}Tc methylene diphosphonate. An area of high intensity of uptake is shown in the left mandible. The uptake is extending up in the condyle.

images is also useful for the detection of mandibular osteomyelitis.²⁸

Head and neck cancers are sensitive to radiation. Radiotherapy alone, or combined with surgical resection is part of the treatment and especially the mandible may be included in the radiation field.²⁹ Osteoradionecrosis can be defined as radiological evidence of bone necrosis within the radiation field, where tumor recurrence has been excluded.²⁹ It has been suggested that microorganisms play a very minor role in the pathophysiology of osteoradionecrosis of the jaws, differentiating it from osteomyelitis.³⁰ The radiological findings are cortical thinning and destruction, sclerosis, sequestration, and loss of cancellous bone.³¹ CT is superior to panoramic radiography in visualizing the features and extent of osteoradionecrosis of the mandible.³¹ Fig. 2.6 illustrates a patient with osteoradionecrosis developing several years after radiation therapy. Contrast-enhanced MRI can be used to better show the bone marrow involvement as marked contrast enhancement of the osteoradionecrotic bone marrow is shown.³²

Cysts and benign tumors

Radicular cysts are the most common cysts found in the jaws, followed by dentigerous cysts and odontogenic keratocysts.³³ Large cysts in the region of the maxillary sinus may be difficult to image with conventional radiographs and CT is usually indicated to see the extension of the cyst (Fig. 2.7). Dentigerous

Fig. 2.6 The patient was treated with radiation therapy 9 years ago for a cancer in the tonsil region. He now has pain in the right side of the mandible. (a) Panoramic radiograph showing bone destruction in the right mandibular molar region and mandibular ramus. (b, c) Cone-beam CT shows the large extent of the bone destruction in a bucco-lingual direction.

cysts and keratocysts are usually incidental findings in panoramic radiographs, with keratocysts predominantly found in the mandible (Fig. 2.8). In the most recent WHO classification, the odontogenic keratocyst has been identified as an odontogenic tumor and it was named keratocystic odontogenic tumor.³⁴ CT may be indicated to locate the relation of the mandibular canal to the cyst and teeth (Fig. 2.9). Benign tumors are relatively uncommon lesions in the oral and maxillofacial region. There is, however, a significant geographical difference in prevalence, e.g. the ameloblastoma occurs most frequently in all Asian,

Fig. 2.7 Patient with a fistula in the maxillary right canine region. Buccal swelling and symptoms of sinusitis. He mentions that a tooth was extracted in the region about 10 years ago when he had similar symptoms. The final diagnosis was proved to be residual cyst. (a) Panoramic radiograph which is difficult to interpret. (b) CT with an axial section showing well defined bone destruction in the right maxillary canine region. (c) Coronal section showing the cystic lesion with thickened bone around the cyst. Soft tissue swellings are seen in the maxillary sinus. (d) Axial CT taken 10 years earlier, when the patient had symptoms of sinusitis. A cystic lesion is seen around the root tip of the right maxillary canine. The tooth was later extracted.

African and South American countries.³⁵ Sometimes it is difficult to differentiate cysts and tumors on the basis of conventional radiographs. MRI could be helpful to differentiate between cysts and tumors.³⁶

Fig. 2.8 Panoramic radiograph showing a multilocular bone destruction in the right mandibular ramus area. The patient had no symptoms and the cyst was detected in bitewing radiographs taken by his dentist. The tentative radiological diagnoses were ameloblastoma or odontogenic keratocyst. The diagnosis from the pathologist's report was odontogenic keratocyst.

Malignant tumors

Primary malignant bone tumors are uncommon in the jaws. Squamous cell carcinoma is the most common head and neck cancer and it may invade the underlying bone. The typical appearance on a panoramic radiograph of a malignant lesion involving the jaw bone is bone destruction with a border that is ill defined. Fig. 2.10 shows an example of a carcinoma of the maxillary sinus involving the upper jaw detected on a panoramic radiograph. Rapidly growing malignant lesions destroy the alveolar bone and usually no root resorption is present. A typical sign is that the teeth may appear to be floating in space: "floating teeth". Some malignant tumors such as osteosarcomas and chondrosarcomas can produce hard tissue with irregular margins. The posterior part

Fig. 2.9 A cystic lesion that at surgery was diagnosed as a traumatic bone cyst. (a) Panoramic radiograph showing the cystic lesion in the right mandibular premolar and first molar regions. (b, c) Cone-beam CT was performed to locate the mandibular canal. The lingual cortical bone is thin. In the anterior section the mental foramen and mandibular canal are visualized.

Fig. 2.10 The patient complains of pain in the upper left jaw. A swelling of the left cheek is noticed. (a) Panoramic radiography shows an ill defined bone destruction in the area of the left maxillary sinus and the edentulous jaw seems to be involved in the bone destruction. (b, c) Contrast-enhanced axial CT sections showing bone destruction of the anterior and medial walls of the maxillary sinus and of the alveolar bone. The tumor is expanding buccally into the cheek. (d) Coronal section showing complete destruction of the jaw. The superior bony wall to the orbit seems intact.

of the mandible is the most common location of metastatic tumors in the jaws and for females the most common site of origin is the breast and for men the prostate.³⁷

The radiographic examination of malignant tumors often comprises CT and MRI to determine the extent of the tumor and to evaluate cervical lymphadenopa-

thy.³⁸ Post-treatment examinations are usually performed to evaluate the effect of treatment. Recently, a combination of CT and positron emission tomography (PET) has been introduced and PET/CT is now widely used as an advanced clinical tool for the diagnosis, staging, and restaging of cancer, and for the assessment of tumor therapy.³⁹

Temporomandibular joint (TMJ)

The majority of patients with temporomandibular disorders (TMD) achieve good relief of symptoms after conservative therapy.⁴⁰ Imaging of TMD patients plays a minor role in the management of these patients as it has been shown that the treatment outcome is not affected by the radiological findings.⁴¹ Despite the success of conservative care, some patients do not improve and TMJ surgery may be indicated.⁴² In these cases radiography is indicated, as well as in patients with trauma, tumors, ankylosis and developmental anomalies. Further, radiographic examination of patients with polyarthritic conditions, such as rheumatoid arthritis, can be recommended to evaluate the degree of joint destruction.⁴³ Bone scanning with ^{99m}technetium phosphate might be indicated to determine the level of growth activity in condylar hyperplasia.⁴⁴

There are different techniques for imaging the TMJ: panoramic radiography, plain radiography, conventional and computed tomography, arthrography, and MRI. Panoramic radiography is not a reliable method of accurately showing the shape of the mandibular condyle⁴⁵ and the temporal component is poorly visualized. Plain radiography of the TMJ depicts the mineralized part of the joint, but superimposition of adjacent anatomic structures can make interpretation difficult. Conventional tomography improves the depiction of the bone structures.⁴⁶ However, minor bony changes will not be shown in conventional tomography.⁴⁷ A conventional tomo-

Fig. 2.11 The patient has pain and crepitation from the left TMJ. The sagittal tomogram obtained with hypocycloidal tomography shows flattening, sclerosis and an anterior osteophyte of the condyle. The articular eminence is also flattened. The diagnosis is osteoarthritis.

gram from a patient with osteoarthritis is shown in Fig. 2.11. CT imaging provides exquisite detail for bony abnormalities, such as ankylosis, fractures (Fig. 2.12), osseous tumors and arthrosis⁴⁸ and 3D images can be produced; 3D reconstructions of a patient with condylar aplasia are shown in Fig. 2.13.

MRI has gradually replaced arthrography and information about disk position, joint fluid, bone marrow changes, and bone structure at multiple levels of the joint can be obtained from MRI. MRI is emerging as the prime diagnostic imaging technique in TMD patients.⁴⁸ The technique, however, is expensive and there are no studies showing when the results of the MRI examination will result in a better treatment outcome for the typical TMD patient.⁴⁹ Imaging of the TMJ is definitely indicated prior to TMJ surgery and the preferred method is MRI if the soft tissue should be shown and CT if the hard tissue is of prime interest. In cases of tumors the methods often are combined.

A classification system for disk displacement was developed by Tasaki *et al.*⁵⁰ Disk displacement presents as a spectrum of displacements in all directions with anterolateral and anterior disk displacement being the most common.⁵⁰ A combination of sagittal and coronal MR images will show anterior as well as sideways disk displacements.⁵¹ A systematic review of MRI of the TMJ concluded that the most commonly used MRI technique was a combination of sagittal and coronal images using proton density and T2 sequences.⁴⁹ Fig. 2.14 illustrates a patient with anterior disk displacement without reduction. The presence of joint effusion can be seen in the T2-weighted image in Fig. 2.14b, but the diagnostic value of this finding is not clear from the literature. Fig. 2.15 illustrates a case with changes in the bone marrow where both cone-beam CT and MRI have been used.

Fig. 2.12 Cone-beam CT of a fracture of the condylar neck after a bicycle accident. Upper left, sagittal view; upper right, coronal view; lower right, axial view. The condylar fragment has been dislocated medially and inferiorly. The images are taken with 3D Accuitomo (Morita corp.).

Fig. 2.13 CT 3D reconstructions of a patient with hemifacial microsomia and aplasia of the right condyle. The patient is missing the ear and a defective zygomatic arch is seen on the right side. The left side has developed normally.

Fig. 2.14 The patient has pain from the right TMJ and difficulty in opening the mouth wide. (a) Proton density MR image taken at intercuspal position. The disk is anteriorly displaced. (b) T2-weighted image showing an area with bright signal in the upper joint space: joint fluid. (c) Maximum mouth opening. The disk is situated anterior of the condyle: anterior disk displacement without reduction.

Implant treatment

Panoramic radiography is the first choice for the radiological appraisal before implant treatment. The technique is, however, dependent on proper positioning of the patient during exposure and objects located outside the center of the sharply depicted plane are reproduced with distortions. Reliable measurements have been found for digital panoramic radiography,⁵² but both over-⁵³ and underestimation⁵⁴ of vertical linear measurements have been found in other studies of panoramic radiography. The inherent errors in panoramic radiography should always be kept in mind whenever an exact assessment of a distance is required. Panoramic radiography is inferior to conventional tomography and CT in visualization of the mandibular canal and in measurements related to the mandibular canal.^{55,56} For proper preoperative planning of oral implants, the need has increased for cross-sectional tomographic examinations.⁵⁷ The use of tomography increased the efficacy of periapical and panoramic images, with respect to the prediction of the appropriate implant size when planning single

tooth implants.⁵⁸ CT has today almost totally replaced conventional tomography in oral radiology, although conventional tomography still may be in use for cross-sectional imaging. There is a choice between multislice CT and cone-beam CT for preoperative examination of implant patients. Loubéle *et al.*⁵⁷ found no significant differences between multislice CT and cone-beam CT when measuring distances on dry skulls. Cone-beam CT should be preferred as this technique gives lower radiation dose compared to multislice CT. However, when a completely edentulous patient is examined several exposures with cone-beam CT with a narrow field size are necessary and in such cases multislice CT should be preferred (Fig. 2.16). CT is indicated whenever the bone volume must be evaluated accurately and when localizing the mandibular canal. Fig. 2.17 shows cone-beam CT of the mandibular canal. Another indication of CT is when evaluating bone grafting, as two-dimensional radiographs underestimate bone resorption.⁵⁹ Postoperative follow-up examinations after implant treatment are usually performed with intraoral radiographs taken in a standardized way.

Fig. 2.15 Cone-beam CT and MRI of a patient with symptoms of osteoarthritis of the right TMJ. (a) Cone-beam CT showing a subchondral cyst in the lateral part of the condyle. Upper right, axial section; lower left, sagittal section; lower right, coronal section. (b) MRI, proton density coronal image showing the cyst with medium signal intensity. (c) T2-weighted coronal image showing the cyst with high signal intensity. Joint fluid (high signal intensity) is also seen in the lateral part of the lower joint compartment.

Fig. 2.16 Multislice CT examination for planning of implant treatment of an edentulous maxilla. (a) Panoramic radiograph. The bucco-palatal bone width of the maxilla was judged to be questionable. (b) 3 mm thick paraxial reconstructions made perpendicular to the alveolar bone (cross-sections) of the left side from the incisor to the premolar region. The images are produced in scale 1:1. B = buccal, L = lingual. (c) 3 mm thick panoramic reconstructions. The number of the vertical lines can be identified in the paraxial sections in order to locate the section.

Fig. 2.17 Cone-beam CT of the mandible to visualize the mandibular canal. Images are produced in scale 1:1. (a) Anterior section showing the mental foramen (coronal section, lower right). (b) Posterior section in the molar region showing the mandibular canal (coronal section, lower right).

Chapter 3

Medical Aspects – High-risk Patients

Earl G. Freymiller

Underlying medical conditions can place patients at increased risk during surgery. This chapter covers several high-risk diseases commonly found in patients undergoing oral and maxillofacial surgery. Divided into major organ systems, each system will discuss one or two specific diseases with oral and maxillofacial surgical implications. Some diseases increase the risk of surgical complications (e.g. bleeding in von Willebrand's disease, wound infection in immunocompromised patients). For other diseases, the surgery itself can affect control of the underlying disease (e.g. surgical stress and its effect on coronary artery disease, diabetes mellitus, etc.).

Cardiovascular system

Ischemic heart disease

In ischemic heart disease, the mismatch between myocardial oxygen supply and demand places patients at increased risk when undergoing oral and maxillofacial surgery. During an anginal attack, the myocardial ischemia causes a temporary decrease in the effectiveness of the cardiac pump, in addition to placing the patient at risk for the initiation of a cardiac arrhythmia. More severe hypoxia resulting in myocardial infarction causes necrosis of part of the myocardium which can produce a permanent decrease in cardiac function, initiate congestive heart failure, trigger arrhythmias, or cause death.

The main risk factors for coronary artery disease are hypertension, smoking, diabetes mellitus, dyslipidemia, family history, and obesity. Patients with no prior history of ischemic heart disease but with several risk factors should be considered to have ischemic

heart disease until proven otherwise. Medical treatment of patients with coronary artery disease includes changes in lifestyle (weight loss, smoking cessation, exercise, etc.) and controlling other medical risk factors (diabetes, hypertension, dyslipidemia). Medical therapy includes aspirin to help decrease platelet adhesion and limit thrombus formation, beta-blockers and/or calcium channel blockers to help control the pressure against which the heart must contract and control heart rate, statins to reduce cholesterol, nitrates, and angiotensin converting enzyme (ACE) inhibitors. Surgical treatment is aimed at revascularizing the ischemic heart through percutaneous cardiac angioplasty with stent placement, or coronary artery bypass grafting.

Preoperative evaluation of the patient with ischemic heart disease is aimed at determining the severity of the underlying disease, thus determining the amount of cardiac reserve which directly relates to surgical risk. Much information can be obtained from the medical history, by determining the patient's

ability to tolerate cardiac stress during an exercise like climbing stairs. Specific cardiac tests augment this information. A preoperative electrocardiogram (EKG) may be of some use (e.g. T waves indicative of prior myocardial infarction). However, the resting EKG can be completely normal between ischemic events. Thus, a stress EKG gives more information. If the patient cannot exercise, pharmacological stress can be placed on the heart (e.g. dobutamine). Nuclear imaging during stress using thallium and technetium will aid in localizing and determining the extent of ischemic areas, thus increasing the diagnostic sensitivity. Similarly, a stress echocardiogram can detect abnormal wall motion during ischemia, and can also be used to evaluate the extent of any underlying valvular heart disease. Cardiac angiography, although more invasive, identifies the specific location and severity of atherosclerotic plaques restricting blood flow within the coronary arteries.

During oral and maxillofacial surgery and in the immediate postsurgical period, the goal is to prevent cardiac hypoxia. Patients with significant coronary artery disease may not tolerate a decrease in oxygen-carrying capacity; it is believed that the hemoglobin concentration should not be allowed to fall to a level that would be acceptable in an otherwise healthy patient, and thus there is a much lower threshold for transfusion in patients with coronary artery disease. Some studies have demonstrated that a low hemoglobin level increases the postsurgical mortality rate in patients with cardiac disease.¹ However, prospective, randomized clinical trials have demonstrated that restricting transfusions to maintain the hemoglobin concentration at 7–10 g/dl (as opposed to 10–12 g/dl) actually results in decreased mortality in some groups of critically ill patients (those less acutely ill and those less than 55 years of age).² For patients with clinically significant cardiac disease, no difference in mortality was seen when patients' hemoglobin levels were allowed to drop to the 7–10 g/dl range. Except for those patients recovering from an acute myocardial infarction or those with unstable angina, restricting transfusions may actually be beneficial.² Besides possible disease transmission or transfusion reactions, there are other concerns associated with transfusion. Immunomodulation resulting from allogeneic transfusions has been shown to increase the risk of postsurgical bacterial infections.³ Especially important to the oral and maxillofacial surgeon, some studies have implied that allogeneic transfusions increase the risk of tumor recurrence after surgery for head and neck cancers,⁴ and/or shorten the time to recurrence,⁵ also due to down-regulation of the immune system. All of these factors must be considered when deciding whether or not to transfuse the patient with ischemic heart disease.

Fluid overload which results in increased cardiac workload must be avoided in patients with ischemic heart disease. Consideration should also be given to

cardioprotective perioperative beta-blockade to reduce heart rate and control after-load, thus decreasing oxygen consumption by the heart. Perioperative beta-blockers are probably beneficial for high cardiac risk patients (more than one clinical risk factor), but their use is uncertain for those with a single risk factor.⁶ Unless significant bleeding will represent a major problem for surgery, many recommend continuing daily low-dose aspirin through the pre- and postsurgical periods, because aspirin withdrawal precedes up to 10.2% of acute cardiovascular events, with the mean time to occurrence of a cardiac event after aspirin withdrawal being just over a week (8.5 days).⁷

For an acute ischemic event in the postoperative period, patients should be treated with supplemental oxygen and nitrates. An EKG may demonstrate flipped T waves, the development of Q waves, and ST changes. Elevation of cardiac-specific markers such as creatinine kinase-MB and troponin indicate myocardial infarction. Pain control (morphine) and anti-platelet therapy (aspirin) should be administered. Consideration of low molecular weight heparin and possible early percutaneous transluminal coronary angioplasty (PTCA) or thrombolysis (tissue plasminogen activator, t-PA) is indicated. Beta-blockers in combination with calcium channel blockers should also be considered.

Valvular heart disease

The patient with valvular heart disease undergoing oral and maxillofacial surgery presents two main concerns. The first concern is for the decreased effectiveness of the cardiac pump. The second is for the patient's increased risk for developing bacterial endocarditis. Patients with valvular heart disease frequently present with a heart murmur graded from 1 to 6. However, the louder murmur is not always indicative of a more severe problem. Valvular heart disease is initially diagnosed with a stethoscope, by determining where on the chest wall the murmur is heard loudest, in which part of the cardiac cycle it occurs (systole or diastole), the quality of the murmur (e.g. crescendo-decrescendo), and where it radiates. However, the final diagnosis is almost always confirmed with an echocardiogram.

In mitral stenosis, the stenotic mitral valve reduces left ventricular filling so cardiac output is decreased and left atrial pressure is increased. The condition can worsen when the patient becomes tachycardic. Tachycardia decreases the time for left ventricular filling, and cardiac output can fall. Perioperative tachycardia should thus be avoided in patients with mitral stenosis. The resultant left atrial enlargement also predisposes the patient to develop atrial fibrillation. Atrial fibrillation with mitral stenosis requires anticoagulation therapy to reduce the risk of embolic stroke. With mitral regurgitation, the incompetent mitral valve also decreases cardiac output, as a por-

tion of blood flows back into the left atrium during systole. This can also result in an enlarged left atrium, and predisposes the patient to atrial fibrillation. Aortic stenosis is of special concern. The limitation to left ventricular outflow not only reduces cardiac output, but also causes significant left ventricular hypertrophy with a concomitant increase in myocardial oxygen demand. Frequently fatal if left untreated, aortic stenosis presents a significant surgical risk. With aortic insufficiency, systemic blood flows back into the left ventricle during diastole resulting in left ventricular dilation (but not necessarily hypertrophy) and an increase in stroke volume. Patients may present with an increased systolic pressure, but with retrograde regurgitant flow during diastole, the pressure rapidly drops and systemic diastolic pressure is low. Therefore, an enlarged pulse pressure is seen with bounding carotid pulses.

Treatment of valvular heart disease is directed toward controlling blood pressure and heart rate, and in treating any accompanying congestive heart failure (e.g. diuretics). Surgical treatment includes valvuloplasty (possibly via cardiac catheterization) or valve replacement with subsequent anticoagulation. The American Heart Association guidelines for prevention of bacterial endocarditis in patients with valvular heart disease now only include antibiotic prophylaxis for patients at the very highest risk. Patients recommended for coverage include those with prosthetic valves (or other prosthetic material used to repair a valve), patients with unrepaired cyanotic congenital heart defects (and those with residual defects after repair), those within 6 months of repair of a congenital heart defect, patients with a prior history of infective endocarditis, and those who develop valve defects after cardiac transplant.⁸

Congestive heart failure

Insufficient cardiac output results in increased back pressure with fluid overload in the pulmonic vascular system. Congestive heart failure has approximately a 50% 5-year mortality rate.⁹ Causes of congestive heart failure are multiple, and include long-standing hypertension, prior cardiac damage secondary to infarction, valvular heart disease, congenital heart diseases, etc. Congestive heart failure usually begins with left-sided failure. The pulmonary fluid overload causes rales, dyspnea on exertion, shortness of breath, fatigue, weakness, paroxysmal nocturnal dyspnea, and orthopnea. These symptoms are worsened at times of exertion or with gravitational patient positioning. Long-standing left-sided failure places more workload on the right ventricle and can progress to include right-sided heart failure with jugular venous distention, pitting pedal edema, and liver enlargement from hepatic congestion.

Serum measurements of beta natriuretic peptide released from the right and left ventricular myocytes

during volume and/or pressure overload can help confirm the diagnosis, and is especially useful to rule out other primary pulmonary causes of dyspnea. Beta natriuretic peptide levels are more accurate than the history, physical exam, and other lab tests in identifying congestive heart failure as the underlying cause of dyspnea.¹⁰ Chronic medical treatment for the patient with congestive heart failure includes exercise and weight loss, with fluid and sodium restriction. Medications include ACE inhibitors, beta-blockers to reduce the workload of the heart, diuretics to reduce the fluid volume, and digoxin to improve the cardiac inotropic function.

The oral and maxillofacial surgeon must take into consideration the volume of intravenous (IV) fluids administered to patients with congestive heart failure. Patient positioning during outpatient surgery is important, and the patient should be reclined a limited amount. For an acute episode of pulmonary edema, in addition to supplemental oxygen, the patient should be treated as an emergency with morphine, nitroglycerin, and a diuretic such as furosemide.

Respiratory system

Asthma

The prevalence of asthma is increasing, and it is now the leading chronic illness of childhood.¹¹ In the reactive airway, chronic inflammation of the bronchioles produces edema, smooth muscle contraction, and increased mucus production, all of which contribute to dyspnea and wheezing with cough. Asthma attacks can be triggered by exercise, allergy, exposure to respiratory irritants, or respiratory infections. Some patients will eventually outgrow the disease whereas others may develop it later in life. Chronic treatment is determined by the severity of the disease. For patients with mild and only intermittent attacks of asthma, treatment with a beta-2 agonist inhaler on a PRN basis is employed. If the exacerbations are more frequent but still with mild symptoms, a daily low-dose steroid inhaler is frequently prescribed, using the beta agonist as a rescue inhaler during acute flares. For the patient with somewhat more severe and persistent symptoms, in addition to the daily steroid inhaler and a long-acting bronchodilator, oral leukotriene antagonists or theophylline may be used. The most severe asthmatics may require treatment with oral corticosteroids.

Treatment of an acute asthmatic attack during outpatient oral and maxillofacial surgery should initially be addressed by placing the patient in an upright position and administering oxygen and a beta-2 agonist bronchodilator inhaler such as albuterol. If the symptoms become severe, subcutaneous epinephrine and corticosteroids should be given, with consideration of intubation.

Chronic obstructive pulmonary disease

COPD is usually the direct result of smoking, and more rarely of other inhaled environmental irritants. It commonly occurs as emphysema with destruction of the septae of the small airway spaces resulting in enlargement of the alveoli. Chronic bronchitis presents with persistent bronchial inflammation and increased mucus production causing cough. COPD often presents as a combination of both. Symptoms include shortness of breath, dyspnea, wheezing, and a productive cough. Cessation of smoking will help to reduce surgical anesthetic complications; however a rebound increase in sputum production may initially occur. Thus, a cessation period of 8 weeks is usually needed to minimize the pulmonary risks associated with smoking.¹²

Surgical risks in patients with COPD are not limited to those associated with the respiratory complications during anesthesia. Smokers are at increased risk for other systemic conditions such as myocardial infarction and stroke. Poor wound healing and a greater risk for wound dehiscence and infection are more pronounced in smokers.¹³

Chronic medical management of COPD includes cessation of smoking and the use of bronchodilators (e.g. beta-2 agonists or anticholinergic inhalers), steroid inhalers, and mucolytic agents. In severe cases, portable supplemental oxygen therapy may be required, with systemic oral glucocorticosteroids reserved for acute and severe exacerbations.

Renal system

Renal failure

Normal blood flow to the kidneys is high, around 20% of cardiac output. About 10% of the plasma passing through the renal arteries is filtered in the glomeruli. Renal failure has many causes including long-standing hypertension, diabetes, prolonged hypovolemia or hypoxia. The kidneys are oxygen sensitive, and are one of the early organs to show signs of damage after periods of hypovolemia or hypoxia. Intravenous contrast dye and drugs such as gentamicin and non-steroidal anti-inflammatory medications are nephrotoxic.

Renal disease is usually divided into three categories. Prerenal disease includes any process resulting in a limitation of blood flow to the kidney. Postrenal disease occurs when there is restriction to urine outflow with resultant back pressure into the kidney. Intrinsic renal disease involves direct injury or failure of the kidney filtration system.

For surgical patients with renal disease, close monitoring of urine output is essential. As a rule, appropriate urine output in any surgical patient should be at least 4ml/kg/h for the first 10kg in

patient weight, 2ml/kg/h for the second 10kg, and 1ml/kg/h for each additional kilogram. Therefore, for a 70kg adult, minimum urine output should be about 110ml/h. For patients with renal disease, it is crucial to maintain renal perfusion, so hypovolemic and hypotensive anesthetic techniques should be avoided whenever possible. In addition the surgeon should avoid contrast dye in radiographic studies and avoid or limit the use of nephrotoxic drugs such as non-steroidal anti-inflammatory medications.

For the patient with acute renal failure, low-dose dopamine (2µg/kg/min) has been used in the intensive care setting in attempt to improve renal perfusion, but the evidence to support its use is weak.¹⁴ Although low-dose dopamine has been shown to reduce renal vascular resistance in patients without acute renal failure, in those with acute renal failure low-dose dopamine can actually worsen renal perfusion.¹⁵

Uremia affects platelet function, so bleeding may be prolonged in patients with chronic renal failure. To reduce the risk of bleeding in patients on dialysis, elective oral and maxillofacial surgery should usually be scheduled for the day following dialysis when risk of uremia is low; dialysis is resumed 2 days after surgery at which time dialytic heparinization should be safe from a surgical hemostatic standpoint.

Endocrine system

Diabetes mellitus

Of all the endocrine diseases, diabetes mellitus is probably of most concern for the oral and maxillofacial surgeon. It is one of the most commonly encountered endocrine disorders in surgical patients. Not only can diabetes affect the outcome of surgery (e.g. increased risk of infection), the stress of surgery can affect the control of the disease, especially in the brittle diabetic patient. Diabetics are also at increased risk for many other systemic diseases such as coronary artery disease, cerebrovascular accidents, renal failure, etc.

Type 1 diabetes typically occurs in younger patients and is the result of autoimmune destruction of the beta cells of the pancreas. Hence, type 1 diabetic patients require exogenous insulin, either injected subcutaneously or via an insulin pump. Type 2 diabetes, which often occurs later in life, is due to insulin resistance at the target cells and is often followed by failure of the beta cells to fully compensate and produce sufficient insulin. As type 2 diabetes may develop in association with excessive weight gain, it may be completely or at least partially controlled with weight loss. Oral agents are used to control blood sugar in the type 2 diabetic patient, but insulin may be required for full control.

Exogenous insulins are classified primarily based on their time to onset and length of action. They are

classified as rapid acting (e.g. regular insulin, peak effect 2–4 hours), intermediate acting (e.g. NPH or lente, peak effect 6–12 hours) and long acting (e.g. ultralente, peak effect 10–16 hours) and are frequently used in combination. All insulin marketed in the USA is human insulin produced by genetically engineered *Escherichia coli*. Lantus is long acting and humalog and novalog are short acting. Nasally inhaled insulin is also available, but has only about 10% of the activity of subcutaneous insulin, is affected by smoking, and may cause pulmonary changes.

Oral agents for type 2 diabetes are targeted at various points in the glucose metabolism pathway. The sulfonylureas (e.g. glyburide, glipizide) act to increase insulin production by the beta cells. Biguanidines (e.g. metformin) act to decrease glucose production by the liver and increase glucose uptake in the periphery by sensitization of peripheral tissues to insulin. The alpha-glucosidases inhibit intestinal polysaccharide breakdown. Thiazolidinediones act to improve endogenous insulin sensitivity in target organs. Oral medications can also be used alone or in combination to control blood sugar in people with type 2 diabetes.

Blood sugar must be closely monitored and controlled in the perioperative period. A preoperative glycosylated hemoglobin level (HgA1C) will give an indication of the degree of blood glucose control over the prior 2–3 months, and thus is a better indicator of possible chronic sequelae of diabetes (e.g. coronary artery disease, diabetic nephropathy) than is one isolated fasting blood sugar value. A target value for glycosylated hemoglobin is less than 7%. However, in the perioperative period, serum glucose levels must be frequently monitored and controlled. This may be difficult in the brittle diabetic patient due to various surgical factors (surgical stress, nil per os (NPO) status, etc.) and so no standard regimen can be used by the oral and maxillofacial surgeon that will fit every diabetic patient.

Consideration must be given to the patient's overall diabetic status (well controlled versus brittle), timing of the procedure (preferably first case in the morning), length of the procedure, and time until oral intake can resume (especially important in patients undergoing oral and maxillofacial surgery). Often, short-acting insulin or short-acting oral medications are held on the day of surgery and longer-acting agents are given at a reduced dose. In the brittle diabetic patient these decisions should be made in consultation with the patient's endocrinologist. In the perioperative period, patients with type 1 diabetes are controlled with a sliding scale insulin dosage schedule.

Those patients with type 2 diabetes often require an insulin sliding scale during the immediate postoperative hospital stay. Dietary caloric control, while maintaining adequate nutrition for healing, is also important during hospitalization.

Gastrointestinal system

Liver failure

Due to the numerous functions of the liver, surgery presents an especially high risk for patients with reduced hepatic function. Liver failure can be a direct result of hepatitis, ethanol abuse, medications, etc. The liver functions to metabolize toxins and drugs, produce and excrete bile, synthesize proteins such as albumin and clotting factors, regulate metabolism (e.g. gluconeogenesis), etc. All of these functions are crucially important in the surgical patient.

Special consideration must be given to the patient in liver failure about to undergo surgery. The interval between dosing of medications may need to be increased due to slower metabolism of certain drugs. Hepatotoxic medications such as acetaminophen should be avoided. Patients with compromised liver function are at risk for poor wound healing. As serum albumin levels fall, wound healing becomes compromised. A more sensitive nutritional marker than albumin, serum prealbumin levels should be measured prior to surgery in patients with chronic liver failure. Since prealbumin is not a precursor of albumin, the more accurate name is transthyretin (serum transport protein for thyroxine and retinol-binding protein).¹⁶ (It was originally called prealbumin only because it preceded albumin on gel electrophoresis.) Since serum prealbumin levels respond more rapidly than albumin (due to albumin's longer half-life and larger body pool) prealbumin is a more sensitive test for monitoring changes in nutritional status. Low levels (<10 mg/dl) correlate with an increase in surgical blood loss, morbidity, and mortality.¹⁷

Control of bleeding is also a concern in the patient with liver failure. With the exception of factor VIII which is also produced by endothelial cells, all of the clotting factors are produced by the liver. Since bile is needed for vitamin K absorption, the vitamin K dependent clotting factors (II, VII, IX and X) are especially limited. Portal hypertension secondary to hepatic failure can cause splenomegaly, with associated platelet sequestration. The resultant thrombocytopenia further compromises blood clotting and can contribute to excessive surgical bleeding. For a patient in liver failure who has an international normalized ratio (INR) greater than 1.5 or platelet count less than 50 000, consideration should be given to transfusion of fresh frozen plasma and/or platelets prior to surgery.

Hematologic system

Disorders of hemostasis

The main components of blood include cells (red blood cells (RBCs), white blood cells (WBCs)), cellu-

lar particles (platelets), proteins (albumin, globulin, coagulation proteins, etc.) and serum. In surgery consideration certainly must be given to the quantity and quality of red cells for adequate tissue oxygenation and white cells to adequately prevent, resist, and/or combat infection. However, of all health care providers, it is the surgeon who is most influenced by the blood's ability to clot. Therefore, recognition and treatment of underlying bleeding disorders are of utmost concern to the oral and maxillofacial surgeon.

Put simply, blood clotting consists of primary hemostasis, where platelet aggregation forms the initial plug, followed by secondary hemostasis, where the plasma coagulation factors cascade to form the cross-linked fibrin clot. Both quantitative and qualitative defects of platelets and/or coagulation proteins produce disorders of hemostasis. These defects can be inherent to the platelets or clotting factors, secondarily acquired from other underlying medical conditions or iatrogenically induced.

Quantitative platelet disorders

Some inherent diseases causing thrombocytopenia include immune thrombocytopenia purpura (ITP) and thrombotic thrombocytopenia purpura (TTP). Examples of thrombocytopenia acquired secondary to other medical disorders include sequestration of platelets in patients with splenomegaly, failure of platelet production in myeloproliferative diseases such as leukemia, and acquired immunodeficiency syndrome (AIDS)-related thrombocytopenia, thought to be due to the effect of human immunodeficiency virus (HIV) on megakaryocytes. Iatrogenically induced thrombocytopenia occurs with bone marrow suppression from chemotherapy and is sometimes seen as a complication of heparin therapy. Treatment for thrombocytopenia usually involves platelet transfusion.

Qualitative platelet disorders

An inherent qualitative platelet disorder occurs with von Willebrand's disease. von Willebrand's factor has roles both in platelet adhesion and in stabilizing factor VIII, so patients with von Willebrand's disease have a qualitative platelet adhesion disorder. A qualitative platelet disorder secondary to another medical condition is seen in uremic patients with renal failure who demonstrate decreased platelet adhesion. Iatrogenically induced alterations in platelet quality occur with clopidogrel (Plavix) and with non-steroidal anti-inflammatory medications. (Of these, aspirin is of special concern because its effect on platelet adhesion is irreversible. To reverse aspirin's effect, sufficient time must pass after stopping the aspirin to allow for production of an adequate number of new platelets.) Treatment of qualitative platelet problems

usually involves treating the underlying etiology (e.g. dialysis to correct uremia or abstinence from aspirin for 7–10 days prior to surgery). For von Willebrand's disease, DDAVP (desmopressin, a synthetic analogue of vasopressin) can be effective, as it induces the release of von Willebrand's factor from endothelial cells, resulting in a virtually immediate increase in von Willebrand factor.¹⁸

Disorders of coagulation factors

With respect to the coagulation factors, many inherent conditions exist. The more common include hemophilia A (factor VIII deficiency), hemophilia B (factor IX deficiency), and von Willebrand's disease (instability of factor VIII). These inherent coagulopathies are corrected with the appropriate recombinant replacement factor (VIII or IX), with fresh frozen plasma or with cryoprecipitate. In addition to causing the release of von Willebrand's factor from endothelial cells, DDAVP also causes factor VIII release from the liver, resulting in a three- to five-fold increase in plasma factor VIII within 30 minutes of its administration,¹⁹ so DDAVP may be useful in hemophilia A (but not B). von Willebrand's disease has several subtypes, and DDAVP is useful for some subtypes but not others. Other medical conditions affecting the coagulation proteins include vitamin K deficiency and chronic liver failure as previously described. Iatrogenically induced coagulopathies are seen with the effects of warfarin (affecting the extrinsic pathway of coagulation and measured with prothrombin time (PT) and INR) and with heparin (affecting the intrinsic coagulation pathway, and measured with activated partial thromboplastin time (PTT)).

For patients with hematologic conditions predisposing them to excessive bleeding, the oral and maxillofacial surgeon can also consider local measures to prevent the subsequent breakdown of clots. For example, epsilon aminocaproic acid and tranexamic acid (antifibrinolytic agents) can both be used topically as an intraoral mouthwash.²⁰

Immunologic system

HIV/AIDS

HIV is a retrovirus that attaches to the CD4 receptor of host cells, including leukocytes, causing a defect in cell-mediated immunity. The immunocompromised patient is at risk for opportunistic bacterial, viral, fungal, and protozoal infections (e.g. pneumocystis or mycobacterium pneumonias, fungal infections, etc.) and at increased risk for cancer (e.g. Kaposi's sarcoma, non-Hodgkin's lymphoma). HIV, transmitted by blood-borne mechanisms and sexual contact, affects multiple organ systems, with cardiac and respiratory complications, neurologic sequelae (e.g. AIDS-related

dementia), kidney effects (e.g. HIV-associated nephropathy), hematologic effects (e.g. AIDS-related thrombocytopenia), etc. Although the time from initial HIV exposure to the development of AIDS can vary tremendously, the median incubation period is reported to be about 10 years.²¹ Drugs used to treat HIV/AIDS are aimed at inhibiting reverse transcriptase, inhibiting viral proteases, and blocking HIV entrance into cells.

Two specific tests are commonly followed in patients with HIV/AIDS. Measurement of viral load is important, not only to diagnose the disease, but also to monitor the effectiveness of antiviral therapy. The level of immunocompromise is evaluated with the CD4 count, which is inversely correlated with the risk for opportunistic infection. The CD4 count is also important for determining when to initiate certain antiviral therapies. A normal CD4 count is greater than 600 cells/ μ l. In the asymptomatic patient, antiviral therapy may be recommended when the CD4 count drops below 350 cells/ μ l.

For AIDS patients undergoing elective oral and maxillofacial surgery, certain preoperative lab tests are recommended. These include a complete blood count (CBC) with platelets, liver function tests with coagulation studies, blood urea nitrogen (BUN) and creatinine to evaluate HIV-associated nephropathy, chest radiography and EKG to evaluate any cardiorespiratory complications, and a CD4 count to determine the patient's immune status.²² For patients with low or no detectable viral titers and normal CD4 counts, no specific precautions need to be taken for surgery. However, patients with suppressed CD4 counts should be covered with prophylactic antibiotics.

Neurologic system

Seizure disorders

Seizures present in various forms. They can be generalized or localized, tonic-clonic (grand mal) or absence (petit mal). Generalized tonic-clonic seizures can result from many conditions such as high fever (especially in children), cerebral hypoxia, intracranial space-occupying lesions (e.g. brain tumor), head trauma, stroke, meningitis, drug withdrawal (e.g. ethanol), local anesthesia overdose, etc. Epilepsy is recurrent seizures due to abnormal cortical neural pathway activation.

Medications (barbiturates, benzodiazepines, hydantoins, succinimides and others) are the first-line treatment for epilepsy, used either alone or in combination. Other treatments include implantation of a vagal nerve stimulator, use of a strict ketogenic diet, and neurosurgical ablation.

Prior to elective surgery on a patient with epilepsy, the oral and maxillofacial surgeon should confirm

that the patient has been compliant with prescribed antiseizure medications, as there is an increased risk of seizure, including status epilepticus, with acute withdrawal of antiseizure medications. In addition, the surgeon may want to confirm that blood levels of the antiseizure medications are in the therapeutic range.

Treatment of a seizure that occurs in the outpatient surgical setting includes administration of a benzodiazepine (e.g. diazepam 5–10mg or midazolam 2–4mg), protection of the patient from injury during the event, and supportive care in the postictal period. Immediate medical evaluation is not always required, but should be considered for a first-time seizure (to rule out other underlying etiologies), if the patient was injured during the seizure, if the patient has persistent mental status changes after the seizure, or if the ictal phase of the seizure fails to resolve within about 5 minutes, as status epilepticus carries a 7–39% mortality rate due to cardiovascular and respiratory compromise.²³

Cerebrovascular accident

Strokes result from a sudden decrease in perfusion of a discrete region of the brain, and are caused either by occlusion of a cerebral artery (thrombotic or embolic) or by rupture with subsequent intracranial hemorrhage. The neurologic deficits that ensue (sensory deficits, motor deficits, aphasia, visual loss, loss of consciousness, etc.) depend on the anatomic location of the stroke. Risk factors for stroke include hypertension, diabetes, smoking, dyslipidemia, cardiac arrhythmias, valvular heart disease, use of oral contraceptives, etc. Since a history of stroke or transient ischemic attack is a strong predictor of perioperative stroke, the surgeon should fully investigate and treat the cause of any stroke or transient ischemic attack that has occurred within the previous 6 months.²⁴

If a patient is suspected of suffering a stroke, *immediate* evaluation and implementation of treatment is indicated. According to the Stroke Council of the American Stroke Association/American Heart Association guidelines,²⁵ if intravascular recombinant tissue plasminogen activator (t-PA) is to be used in attempt to dissolve an occlusive clot and allow for cerebral reperfusion, it must be initiated within 3 hours of the onset of the stroke. Imaging studies (computed tomography (CT) or magnetic resonance (MRI)) first will be needed to determine if the stroke is occlusive or hemorrhagic. In the immediate postoperative period, intravascular t-PA may be contraindicated due to increased risk of surgical bleeding; however direct intra-arterial t-PA may be relatively safe.²⁴ For patients with hemorrhagic strokes, supportive care is provided while the blood pressure is controlled. To maintain cerebral perfusion, blood pressure is controlled gradually to avoid worsening the outcome by additional hypotensive ischemia. In

some situations neurosurgical evacuation of the clot may be beneficial.

Musculoskeletal system

Bisphosphonate-related osteonecrosis of the jaws (BRONJ)

Bisphosphonate medications are prescribed for conditions where a reduction in bone resorption is beneficial. The two most common indications are (1) to increase bone density in patients with osteoporosis and (2) to limit the extension of intrabony malignancies and decrease hypercalcemia in patients with primary bone tumors (e.g. multiple myeloma) or metastatic bone tumors (e.g. breast or prostate carcinoma). These medications are most frequently prescribed in oral weekly doses for osteoporosis (e.g. alendronate, risedronate) and monthly IV doses for patients with primary or metastatic bone tumors (e.g. pamidronate, zoledronate). However, annual IV dosing for osteoporosis now is being advocated.^{26,27}

Some patients taking bisphosphonate medications develop areas of non-healing or slowly healing exposed necrotic bone in the jaws. These areas can enlarge, become secondarily infected, and may eventually result in jaw fracture and/or require resection. The American Association of Oral and Maxillofacial Surgeons defines BRONJ as exposed bone in the maxillofacial region that has persisted for more than 8 weeks in a patient who has received bisphosphonate medications and with no history of radiation therapy to the jaws.²⁸

BRONJ can occur spontaneously, or after a surgical procedure that exposes the jaw bone in a susceptible patient. For patients on monthly IV bisphosphonate therapy, approximately half of the cases of BRONJ occur after a dental procedure, and half spontaneously (although half of these may be attributable to uncontrolled periodontitis).²⁹ The risk is very much greater for patients on monthly IV bisphosphonate therapy for control of bone cancer as compared to those taking oral bisphosphonates weekly or monthly for osteoporosis. Risks have been estimated at 5–15% for the former²⁹ but at only 0.7/100 000 per year of drug use for the latter.³⁰ The risk is known to be cumulative, with patients being at increasingly greater risk the longer they have been taking the bisphosphonate. The risk accumulates faster for those on monthly IV forms (zoledronate at approximately 6 months, pamidronate at approximately 12 months) as compared with weekly oral doses (alendronate at about 36 months). However, cases of BRONJ have been seen after only one or two IV doses (author experience). Concurrent factors such as chemotherapy, steroid use, smoking, etc. are felt to increase the risk.

For patients taking monthly IV bisphosphonates, surgical jaw procedures should be avoided whenever

possible. Root canal therapy with crown amputation should be performed for non-salvageable teeth, as opposed to extraction. For patients taking weekly oral bisphosphonates, dentoalveolar surgery is not absolutely contraindicated. In this group, the risk of developing BRONJ is less and the condition is often less aggressive and more easily treated when it does occur. Nevertheless, for elective surgical procedures it may be beneficial to hold the oral bisphosphonate for several months prior to the planned procedure (depending on the length of time the patient has been taking the oral medication) and resume it several months after healing has occurred.

For patients with established BRONJ, conservative treatment is usually recommended. The exposed bone should be kept clean, and oral chlorhexidine rinses prescribed twice daily. Antibiotics are reserved for episodes of acute infection. Conservative debridement of exposed irritating bone can be performed, so long as no periosteum is elevated that exposes additional bone. Aggressive debridement or resection is reserved for the most severe cases (e.g. jaw fracture, infection not controlled with antibiotics). The possibility of holding the bisphosphonate medication can be discussed with the patient's physician, and may lead to resolution over time, especially for patients on oral bisphosphonates.

Chapter 4

Medical Emergency Care

Zachary S. Peacock and M. Anthony Pogrel

- Emergency situations are to be expected in any active surgical practice.
- Cardiac angina, arrest, asthma attacks, anaphylaxis, syncope, hypoglycemia, and seizures are the most common emergencies encountered in the office setting.
- Prevention, the most important component of management of medical emergencies, is discussed.
- Early recognition and diagnosis of various medical emergencies allows for prompt and successful management. The presentation and pathophysiology of various medical conditions are reviewed.
- Treatment of medical emergencies begins in the office, although knowing when to involve emergency medical services is of utmost importance.
- Treatment for the most common medical emergencies is discussed in detail.

Surgical care in the outpatient setting requires knowledge and preparedness in management of medical emergencies. Surveys of both American and Japanese dental practitioners found that between 19% and 44% of dentists were faced with a medical emergency in any 1 year.¹⁻³ If the numbers were limited to oral and maxillofacial surgeons, it is assumed the percentages would be higher. This chapter will discuss recognition and management of medical emergencies as they pertain to the oral and maxillofacial surgeon.

The first step for surgeons is to accept the fact that emergencies do occur. Preparedness requires sufficient time, effort, and money. Surgeons are seeing an increasing number of elderly and medically compromised patients, making emergencies inevitable. It is emphasized that all members of the surgical office staff must be trained to promptly recognize and efficiently perform appropriate duties in emergency situations.

Sempowski and Brison⁴ classified outpatient offices on the basis of risks for medical emergencies. High-risk offices included those that are in a rural or remote location, have no local hospital, perform invasive procedures in the office, frequently give parenteral medications, or have no access to emergency medical services. Also considered high risk are large group or high-volume practices, as well as those exposed to inclement weather. Oral and maxillofacial surgery offices would be considered in the high-risk category due to the invasiveness of procedures, the provision of anesthesia and the often high volume of work in a variety of locations.

Undoubtedly, the best way to manage medical emergencies is before they happen through a thorough preoperative evaluation. The practitioner must consider not only the pathophysiology of a particular patient's medical comorbidity, but also how they will be affected by the stress of the anticipation and experience of a surgical procedure. This chapter will focus on the most common medical emergencies encountered, including angina, cardiac arrest, asthma, syncope, drug hypersensitivity, hypoglycemia, and seizure.

Syncope

The most common medical emergency encountered in the office is syncope. Syncope is defined as the transient loss of consciousness and postural tone leading to spontaneous recovery without neurological deficit. Vasovagal syncope is the most common cause of unconsciousness in the office setting. It can be psychogenic resulting from fright, anxiety, or certain situations such as the sight of blood. Non-psychogenic causes include prolonged standing and dehydration. Although, syncope is usually a benign, self-limiting event, the surgeon must still be vigilant and rule out other more serious etiologies of unconsciousness.

Cardiac causes include obstructive outflow disease including aortic stenosis, hypertrophic obstructive cardiomyopathy, or acute left ventricular failure secondary to myocardial infarction. More commonly, syncope can be the result of acute arrhythmias such as bradycardia. Neurogenic causes of unconsciousness include some types of seizures, transient ischemic attack, migraines, and subclavian steal syndrome. Stroke is an extremely rare cause of syncope and presents with focal neurologic signs and symptoms well in advance of any loss of consciousness.

Orthostatic hypotension can lead to syncope in patients with depleted intravascular volume and can occur as a side-effect of certain drugs such as antidepressants and antihypertensives. Orthostasis also can occur in patients with autonomic instability, such as diabetes mellitus, and prevalence increases with advanced age. Lastly, hypoglycemia is a rare cause of syncope.

Vasovagal or vasodepressor syncope is generally the etiology in young, healthy patients without the above risk factors. Loss of consciousness usually occurs in three stages, with loss of consciousness occurring after a warning or presyncopal stage. The first stage, the presyncopal stage manifests as a feeling of warmth in face and neck, diaphoresis, and pallor. The heart rate may rise significantly while blood pressure often stays near the patient's baseline. As presyncope progresses, the pupils dilate, respiratory rate increases, and the blood pressure and heart rate drop resulting in loss of consciousness. The patient's breathing may be irregular and the patient may gasp or even become apneic. Convulsions may be observed in the hands, legs, or facial muscles and may often be confused for seizure activity. The pulse is thready and blood pressure can drop to extremely low levels. Generalized muscle relaxation occurs and can lead to loss of the airway. The period of unconsciousness can last from seconds to several minutes after placement in the supine position.⁵ If the patient's unconsciousness lasts for more than 5 minutes after being supine, other causes of syncope should be considered, especially if the patient is over 40 years old and had no prodrome to the loss of consciousness.⁶ Postsyncope

or recovery is usually rapid, although pallor, nausea, and diaphoresis often persist along with some confusion or disorientation.⁷

Management

Upon recognition of presyncope symptoms, the procedure should be stopped immediately, and the patient should be placed in the Trendelenberg position and administered oxygen. This can prevent actual syncope or shorten the syncopal episode. If unconsciousness does ensue, one should resort to the basic life support protocol, first calling for help, then assessing the airway, breathing, and circulation. A simple chin lift or jaw thrust will usually open the airway. Failure to lay a syncopal patient flat can result in brain damage or even death.⁸ If breathing and circulation are present, an ampule of ammonia can be crushed under the patient's nose to hasten recovery. If not done already, vital signs should be obtained and a rhythm analyzed. Vasovagal syncope is very unlikely if unconscious lasts beyond 10–15 minutes. Other, more ominous etiologies of syncope are likely and emergency medical services should be activated if this has not been done already. Definitive management of other causes of syncope often requires work-up in an inpatient setting and treatment is for the underlying cause of the syncope.

Chest pain

Chest pain is an exceedingly common complaint in the surgical patient. Given the high prevalence of cardiovascular disease and the ageing population, it accounts for a large percentage of office emergencies. Many etiologies of chest pain exist, although most commonly it results from angina pectoris and myocardial infarction.

Pathogenesis

Coronary artery disease results from atherosclerosis of the coronary arteries that develops in a predictable manner. The progression of atherosclerosis is accelerated by endothelial dysfunction, inflammation, and thrombosis. The advanced atherosclerotic lesion has a core of lipids and necrotic tissue surrounded by a fibrous cap. The fibrous cap is prone to rupture which can lead to further thrombus formation and occlusion and represents the most common cause of the acute coronary syndrome. The complete occlusion of a coronary artery due to ruptured plaque leads to transmural ischemia and eventually infarction of the myocardium. This is represented as an ST elevation myocardial infarction (STEMI) on 12-lead EKG. Non-occlusive thrombus causes ischemia at the distal aspect of the blood flow of the vessel, the subendocardium, leading to non-ST elevation myocardial infarction (NSTEMI).

Patients with classic angina pectoris usually have fixed atherosclerotic lesions resulting in greater than 70% blockage.⁹ Angina results from an imbalance in oxygen supply and demand in the myocardium. Exertion or stress from a surgical procedure leads to higher oxygen demand that cannot be met by a stenotic coronary vessel and leads to ischemia and pain. Coronary blood flow is normally autoregulated over a wide range of perfusion pressures by vasodilation and constriction. The vascular bed beyond a significant stenosis is usually already dilated maximally at rest and cannot adapt to increasing demand. Oxygen demand is determined by heart rate, systolic blood pressure and wall stress, with the latter determined by ventricular pressure, volume and wall thickness. Patients with long-standing hypertension often have hypertrophied myocardium leading to increased wall stress and are often intolerant of increased heart rate or blood pressure.

Diagnosis and history

When presented with a patient with chest pain, the clinician must decide if the pain has a cardiac or non-cardiac origin. Pain secondary to cardiac ischemia is rarely sharp and well localized, rather it is often described as uncomfortable pressure, tightness, or fullness substernally or just left of the sternum. The feeling is most often not described as pain at all, but rather pressure or discomfort. Cardiac pain is usually constant and without respiratory variation. Pain due to angina, classically subsides gradually over 2–5 minutes with adequate rest. If the pain continues, it is more likely due to infarction of the myocardium. The discomfort may radiate to the jaw, shoulders, the medial aspect of the arm and fingers most commonly on the left side. Patients may also be diaphoretic and describe a feeling of impending doom (*angor animi*). Centrally located dyspnea, especially in older patients, is often considered an “anginal equivalent” and could be the only presenting sign of cardiac ischemia.

Non-anginal chest pain can result from other serious conditions including aortic dissection, spontaneous pneumothorax, pulmonary embolism, esophageal spasm or rupture, and musculoskeletal injury (Table 4.1). Pain from aortic dissection usually is tearing and radiates to the back. Pneumothorax is often associated with shortness of breath and hemodynamic compromise if under tension. Pain from a pulmonary embolism is often pleuritic in nature and can, but not necessarily, result in hypoxia. Musculoskeletal pain is reproducibly tender to palpation.

It is often difficult to discern angina from actual myocardial infarction. A diagnosis of angina requires that the patient have a history of angina and the presenting pain must be consistent with the patient’s prior chest pain. In all other scenarios, the pain cannot be attributed to angina and must be treated as myocardial infarction until proven otherwise.

Table 4.1 Cardiac angina vs non-cardiac pain.

	More likely to be cardiac	Less likely to be cardiac
Description of pain	Dull; constant	Sharp, stabbing; intermittent
Onset	Gradual	Rapid
Location	Substernal	Lateral chest wall, back
Associated symptoms	Radiation to left arm or jaw, diaphoresis, nausea, feeling of impending doom	Not present
Reproducibility	On exertion	With inspiration
Tenderness to palpation?	No	Yes, may reproduce pain complaint

Management

After a brief targeted history into the characteristics of the pain, further assessment of a patient with chest pain suggestive of ischemia includes assessment of airway, breathing, circulation, and measuring of vital signs including oxygen saturation. Immediate treatment is aimed at restoring the balance between oxygen supply and demand. Patients experiencing chest pain generally prefer upright or erect positions. As indicated, the surgeon may administer morphine, oxygen, nitroglycerin, and aspirin. This can be easily remembered as the mnemonic MONA.¹⁰ Start oxygen at 4–6 L/min through a nasal cannula. Prior to giving nitroglycerin, assess whether the patient has taken a 5-phosphodiesterase inhibitor such as sildenafil or tadalafil within the last 24 hours, as serious hypotension can result if combined with nitroglycerin. If not, a nitroglycerin tablet or spray (0.4 mg) should be given sublingually every 5 minutes. Anginal pain will likely be relieved by nitrates in 1–2 minutes. One must be aware that the shelf life on nitroglycerin tablets is 3–4 months after opening. If the patient’s tablets are used and fail to relieve chest pain, one should then use nitroglycerin spray from the office emergency kit. Pain that persists despite a dose of metered aerosol nitroglycerin likely represents myocardial infarction. The adult patient with no history of cardiovascular disease that develops chest pain should be considered myocardial infarction until proven otherwise. In addition, patients whose chest pain returns after initially being relieved by nitroglycerin should also be managed as infarction. Emergency medical services should be sought immediately for transfer to a medical center capable of thrombolysis.

While waiting for help to arrive, continue to monitor vital signs. The patient should be kept in the upright or erect position. Aspirin (160–325 mg) should be chewed by the patient. Pain is further treated with IV morphine (2–5 mg) every 5–10 minutes.¹¹ If no IV is available, nitrous oxide can be administered at 35–40% without titration for relief of ischemic pain.¹² The surgeon should prepare to manage complica-

tions of myocardial infarction including acute dysrhythmias and cardiac arrest. Dysrhythmias usually occur within 1–2 hours of MI and can include bradycardia, ventricular fibrillation/tachycardia, or asystole.¹³ Always have an automated external defibrillator (AED) close by and be prepared to implement advanced cardiovascular life support (ACLS). Early transfer to the hospital also allows for better management of complications.

If available, obtain a 12-lead EKG to direct further management. This will allow differentiation into STEMI (ST segment elevation myocardial infarction) representing transmural infarction, NSTEMI (non-ST segment elevation myocardial infarction), and unstable angina. Management of MI in the acute period has improved dramatically. Angioplasty, stenting, or intravenous fibrinolytic therapy can be used to reopen occluded vessels. To be most effective, however, interventions should be initiated as soon as possible as many centers require less than 1 hour from symptom onset for primary angioplasty.¹⁴

Cardiac arrest

Oral and maxillofacial surgeons are treating an increasing number of elderly and medically compromised patients and therefore are more likely to encounter serious medical emergencies including cardiac arrest. Of all cardiovascular deaths in the USA, about half occur out of the hospital. The most frequent etiologies are ventricular dysrhythmias, commonly ventricular fibrillation or tachycardia (VF/VT), which may deteriorate rather quickly to asystole, a rhythm typically refractory to further treatment.^{15,16} See Table 4.2.

Ultimately, the patient that develops an arrhythmia or cardiac arrest needs to be managed in an emergency department with full ACLS protocols. As response times of emergency medical services (EMS) may vary, it is of utmost importance that offices have the tools to manage the initial phases of resuscitation.

Table 4.2 Symptomatic arrhythmias: signs and symptoms of hemodynamic compromise. Adapted from Haro *et al.*, Arrhythmias in the office. *Med Clin N Am* 2006; 90: 417–36.

Symptoms
Lightheadedness
Chest pain/pressure
Dyspnea
Palpitations
Orthostasis
Syncope
Signs
Hypotension
Heart rate >130 or <50 beats per minute
Cyanosis
Cool extremities
Altered mental status
Tachypnea

Unfortunately, the survival to hospital discharge after an out-of-hospital cardiac arrest is dismal. It has been reported that for each minute of untreated cardiac arrest, the probability of successful rhythm conversion decreases by 7–10%.^{17,18} Improvements in survival after sudden cardiac arrest have been related to institution of the “chain of survival” paradigm.¹⁵ The four links of the chain include: (1) early recognition and call for EMS; (2) initiation of basic life support including cardiopulmonary resuscitation (CPR); (3) defibrillation; and (4) ACLS drug intervention. Performing CPR early to increase perfusion and oxygenation will help make the myocardium more amenable to defibrillation or cardioversion. Preparedness for cardiac arrest in the office requires staff basic life support training, a simple office emergency protocol, necessary equipment, and rapid notification of emergency medical services.

The automated external defibrillator

Early defibrillation in cardiac arrest caused by VF/VT is of utmost importance. The automated external defibrillator (AED) is a device that can analyze a cardiac rhythm and instruct a user to deliver a shock when indicated. AEDs use microprocessors to analyze the frequency, amplitude and structure of an electrocardiogram (EKG) signal. Today, nearly all AEDs use biphasic currents to deliver a shock. Studies show that AEDs have a sensitivity for detecting VF/VT of greater than 90% and a specificity of greater than 95%.¹⁹ False positives can occur most likely due to patient movement by a rescuer or secondary to breathing. These errors can be minimized by proper verification of unresponsiveness, apnea, and pulselessness before an AED is used.

All AEDs are used in the following manner:

1. Power on the AED.
2. Attach electrode pads (Fig. 4.1). The right electrode is placed to the right of the sternum and below the clavicle. The left electrode is placed just lateral and inferior to the left nipple about 15 cm inferior to the axilla. The pads must achieve direct contact with the patient’s skin. If hirsute, hair can be removed rapidly with quick removal of an electrode pad.
3. Press “Analyze” to assess the rhythm.
4. State “Clear” and deliver shock if so prompted by the AED.

Successful resuscitation efforts with an AED depend on proper training and maintenance. A recommendation for all offices to have AEDs has been met with some resistance, which is likely secondary to perceived lack of cost-effectiveness. However, AED use has been integrated into all basic life support courses which allow non-physicians to deliver what is thought to be the most important life-saving measure for a patient in cardiac arrest without the

Fig. 4.1 Correct placement of the electrodes for an AED. The right electrode is placed to the right of the sternum and below the clavicle. The left electrode is placed just lateral and inferior to the left nipple approximately 15 cm inferior to the axilla.

requirement of experience and knowledge of complex cardiac rhythms. Importantly, one needs to recognize that defibrillation itself does not restart the heart, but actually terminates all electrical activity so that normal pacemakers can resume activity. Early CPR helps restore perfusion to the myocardium and other organs, which facilitates the heart's ability to then resume its spontaneous rhythm. Despite some controversies, it is these authors' opinion that an AED should be readily available for any office- based surgical practice treating adults that are at risk for sudden cardiac arrest.

General approach to the collapsed patient

Always assess the level of responsiveness of the patient. If some response occurs, check the level of alertness, chief complaint, and vital signs. Further treatment is dictated by the particular abnormality. If the patient is unresponsive, EMS should be notified immediately, ask for an AED and begin the primary survey as for all unresponsive patients as follows:

- **A: Airway.** Assess the airway by first opening the airway with a head tilt–chin lift or jaw thrust maneuver. Inspect the mouth for foreign bodies, vomitus, or blood.
- **B: Breathing.** Keeping the airway open, look, listen and feel for breathing. If the patient is not breathing after opening the airway, give two rescue breaths using a bag–mask.
- **C: Circulation.** Check for a pulse at the carotid artery. If there is no pulse, cardiac arrest is confirmed. Perform cycles of compressions and ventilations. The correct ratio is 30 chest compressions at a rate of 100 compressions/minute followed by two breaths. This cycle should be performed until an AED arrives.

- **D: Defibrillate.** Attach pads of AED and follow AED prompts as it assesses the rhythm. Deliver a shock if indicated by the prompts. Follow each shock immediately with more cycles of CPR.

The priority during cardiac arrest is for high-quality CPR and early defibrillation when indicated (Fig. 4.2). Secondary considerations include advanced airway and IV drug administration. No drug given during cardiac arrest has been shown to improve survival to hospital discharge or improve neurologic function, so CPR should not be delayed for locating and administering drugs.¹⁰

Considerations in transfer of the patient

It is well known that an unstable patient is best cared for in a hospital setting that is fully equipped for medical emergencies. Transfer of patients inherently results in great vulnerability. Efforts by both the surgeon and EMS should be aimed at stabilizing the patient as above before transfer is made.

Asthma

Asthma is a very common disease that affects an estimated 6.7% of adults and 8.5% of children in the USA.²⁰ It accounts for nearly 2 million emergency room visits yearly and approximately 40% of adults with asthma require emergency room care each year.²¹

Pathophysiology

Asthma is characterized by airway hyperresponsiveness leading to bronchiolar smooth muscle constriction, reversible obstruction and inflammation. The most frequent triggers include viral or bacterial respiratory infections, exposure to cold, allergens, irritants such as smoke, as well as exercise. Exposure to emotional distress or medications such as aspirin, non-steroidal anti-inflammatory drugs (NSAIDs), or beta-blockers can also incite an attack.²²

Prevention

Given the high prevalence of asthma throughout the world, the oral and maxillofacial surgeon must always be prepared to deal with an asthmatic emergency. The goal in the management of asthmatic patients is prevention of acute attacks through a careful history and physical examination prior to commencing treatment. The clinician should ascertain the extent of the patient's asthma by finding out about how often they have attacks, baseline peak flow rate, use of inhaled agents including corticosteroids, and if the patient has ever needed emergency care or intubation.

Fig. 4.2 Pulseless arrest algorithm. Adapted from: *Advanced Cardiovascular Life Support, Provider Manual*, 2006.

Emotional distress in fearful patients can trigger attacks and methods to reduce stress should be discussed. Common anesthetic drugs such as opioids and barbiturates can induce bronchospasm in asthmatics and should be used very carefully. Opioids lead to histamine release and barbiturates are thought to sensitize the respiratory reflexes, easily triggering a response in a predisposed patient.⁸ Aspirin sensitivity is present in 21% of adult asthmatics and 5% of child asthmatics²³ and nearly one third of asthmatics with nasal polyps.²⁴ This is thought to be diversion of arachidonic acid down the 5-lipoxygenase pathway

to form leukotrienes with aspirin's inhibition of the cyclooxygenase pathway. Leukotrienes are thought to significantly contribute to bronchoconstriction.²⁵ A significant amount of cross-reactivity exists between NSAIDs and aspirin, and they must also be used with caution in severe asthmatics.⁸

Clinical presentation

A typical asthma attack presents as congestion or tightness of the chest, cough which is often non-productive, and inspiratory and expiratory wheezing.

Some asthmatic patients are very self-aware of increased asthma symptoms while others will not perceive reduced airflow until it is severe. A peak flow meter is vital for differentiating severity of attacks and can be used in the office to assess respiratory compromise.²⁶ The analysis must be compared to the patient's baseline, so obtaining it in the history is crucial.

Patients exhibiting severe airway obstruction often experience increasing dyspnea and have to lean forward, with arms braced using accessory respiratory muscles to assist with breathing. Patients can become diaphoretic, tachycardic, and often hypertensive. Speech becomes very difficult for the patient and occurs in staccato-like short phrases. Upon auscultation, wheezing can be heard due to turbulent airflow through obstructed airways. Also, crackling sounds characteristic of atelectasis due to mucus plugging can be heard. Wheezing has no correlation with severity of attack, however, as the audible sound can disappear with severe narrowing of airways. Hypoxia is a late sign and if present should prompt immediate treatment.

Management

The surgical procedure should be stopped immediately and all materials removed from the mouth of any patient suspected of having an asthma attack. First, one should assess the severity of the attack based on clinical signs above and peak flow measurements. If capnography is available, alveolar carbon dioxide level (PaCO_2) can be assessed. Respiratory drive is increased in these patients and PaCO_2 should be lower than normal. Elevated or even normal PaCO_2 indicates severe airway narrowing and air trapping. Oxygen should be administered and beta-2 agonist administered via metered dose inhaler (MDI) for bronchodilation. The typical drug given is albuterol via MDI. Six puffs of albuterol MDI (90 μg /puff) are recommended and can be repeated every 20 minutes as needed.

The patient with moderate to severe bronchospasm or obstruction that does not adequately respond to bronchodilators is considered to be in status asthmaticus, a true medical emergency. EMS should be alerted immediately. From increased work of breathing, these patients can quickly fatigue, ultimately leading to hypoxia and shock. Epinephrine, a beta-1 and beta-2 agonist, should be injected subcutaneously. It is available as a preloaded syringe as 0.3 ml of 1:1000 dilution. It should only be administered subcutaneously due to its cardiovascular side-effects when given intravenously. Epinephrine can be given every 20–30 minutes for up to three doses. In the severe attack, parenteral administration of glucocorticoids is required to ultimately relieve the airway inflammation, the underlying etiology.²⁷ Although the benefit of administration is not seen for 3–6 hours it is thought to be better to administer corticosteroid early in the

attack.²⁸ Although the ideal dose of corticosteroid remains unknown, a patient in status asthmaticus should be given 125 mg of methylprednisolone or equivalent in the office or once they arrive in the emergency department.²⁹

Patients with severe hypoxia and respiratory failure require intensive care admission and often intubation. Failure of the patient to respond to initial therapy in the office and continued worsening always warrants emergency department evaluation and definitive management.

Hypoglycemia

According to the Center for Disease Control, more than 7% of adults in the USA are known to have diabetes mellitus.³⁰ Complications that can occur include hypoglycemia, diabetic ketoacidosis, and hyperosmolar non-ketotic coma. Generally, in the setting of the surgical office, hypoglycemia is the most worrisome complication due to its acute nature. The hyperglycemic complications are more often the end result of a more chronic hyperglycemic state and only very rarely encountered in the outpatient setting. Hypoglycemia is defined as blood glucose levels less than 50 mg/dl in adults and less than 40 mg/dl in children.³¹

Hypoglycemia most commonly occurs in the patient being treated for diabetes but may also present in the non-diabetic. Hypoglycemia is the most common endocrine emergency in the outpatient setting. In the Diabetes Control and Complications Trial (DCCT), an estimated 10–30% of type 1 diabetics experienced one hypoglycemic episode requiring treatment each year.³² Previous hypoglycemic episodes, lower glycosylated hemoglobin levels, and intensive therapy predicted hypoglycemic events in the study. In the first 10 years of the UK Prospective Diabetes Study (UKPDS), hypoglycemic episodes requiring third-party intervention occurred at an incidence of 1.2% for type 2 patients treated with insulin.³³ Recent studies suggest an incidence of severe hypoglycemia in type 2 diabetes approximating that of type 1 diabetes regardless of treatment.³⁴ Intensive therapy for tight control of glucose is thought to help prevent the microvascular complications of diabetes mellitus, but also increases the incidence of symptomatic hypoglycemia.

Normal physiological response to hypoglycemia

Glucose is the preferred metabolic substrate for the brain, which relies on a continuous supply to meet its energy requirements as it has no ability to store glucose. Multiple counter-regulatory mechanisms oppose insulin's action to increase peripheral uptake of glucose and lower blood glucose. The central nervous system coordinates the response to an acute

drop in systemic blood glucose through the mechanisms of glucagon, cortisol, and epinephrine to maintain glucose supply to the brain. This involves a decrease in the secretion of insulin followed by a concomitant rise in the systemic counter-regulatory hormones which increase glycogenolysis and gluconeogenesis, and also inhibit uptake by insulin-dependent tissue. In concert, these mechanisms limit glucose use by peripheral tissues and increase endogenous glucose production with resultant recovery from hypoglycemia. This process can often be disrupted by various drugs (exogenous insulin and beta-blockers) or disease states (diabetes, liver or renal failure) that can impair the counter-regulatory response and hence impair recovery from hypoglycemia. Diabetics also often have an attenuated sympathoadrenal response that masks the warning signs seen in hypoglycemia and results in an unawareness of hypoglycemia. The lack of signs and symptoms in these patients leads to a substantially increased risk of severe hypoglycemia.³⁵

Surgical treatment provides many opportunities for complications in the diabetic patient including severe hypoglycemia. Although the stress of a procedure will actually increase the counter-regulatory response and raise blood glucose, other factors may lead to hypoglycemia. Surgical treatment often requires NPO status and insulin-dependent patients require adjustment of morning insulin or oral hypoglycemic doses. In addition, maxillofacial surgery will often alter patients' eating habits for variable periods of time, increasing the risk of hypoglycemia if normal hypoglycemic medication doses are used.

Signs and symptoms of hypoglycemia

The initial symptoms of sweating, anxiety, palpitations, hunger, and tremor occur as the blood glucose level drops below 60 mg/dl. Mild cognitive dysfunction is noted in normal subjects at blood glucose levels of around 50–55 mg/dl. Older patients are more likely to have cognitive impairment than younger patients, and are less likely to have other symptoms warning them of the hypoglycemia.³⁶

More severe neurologic symptoms occur with progressive hypoglycemia. Blood glucose levels below 45–50 mg/dl can lead to lethargy and obtundation. Coma can occur at a plasma glucose concentration of about 30 mg/dl, with convulsions and ultimately death below 20 mg/dl.³⁷

Management

An initial blood glucose level should be obtained to determine and document the level of hypoglycemia. This should not delay glucose administration in any way if clinical suspicion is present. The potential detrimental effects of delayed treatment of hypoglycemia far outweigh any ill effect of hyperglycemia, so the

threshold for administering glucose should be low. For the conscious patient it is appropriate to give glucose orally via glucose tablets or glucose-containing fluids, candy, or food (Table 4.3). A reasonable initial dose is 20 g of glucose. If the patient is unable or unwilling to take oral glucose due to combativeness or unconsciousness secondary to the hypoglycemia, parenteral therapy is necessary. Intravenous dextrose, 25 g initially, is preferable. This can be given very quickly via injection of an ampule of 50% dextrose in water (D50W). With high suspicion in an unconscious patient, dextrose should be administered while the airway, breathing, and circulation phases of resuscitation are being completed. The amount of blood glucose increase from one ampule is variable and continued monitoring is important. EMS should be contacted for any patient that becomes unresponsive secondary to hypoglycemia or doesn't respond to administration of dextrose.

Fifty percent dextrose should not be given to infants or young children as it can cause venous sclerosis and lead to severe rebound hypoglycemia. Instead, for children younger than 8 years old, one should use 25% or even 10% dextrose. One can dilute the 50% dextrose in sterile water. The dose for children is 0.5–1 g/kg equating to 2–4 ml/kg of 25% dextrose.

Glucagon can also be administered to raise blood glucose. It can be administered intravenously and is usually given in 1 mg doses. If intravenous therapy is not available, 1–2 mg of glucagon can be given subcutaneously or intramuscularly. The onset of action is 10–20 minutes and peak effect is seen at 30–60 minutes. This may be repeated as needed. One milligram of glucagon has a similar effect on blood glucose as one ampule of D50W. Glucagon, however is ineffective in patients whose hypoglycemia is secondary to ethanol as glycogen stores are depleted.

The clinician must be aware that these urgent treatments raise plasma glucose concentrations only

Table 4.3 Summary of diagnosis and treatment for hypoglycemia. Adapted from: Marx J. *Rosen's Emergency Medicine: Concepts and Clinical Practice*, 6th edn. Philadelphia: Mosby Elsevier, 2006.

1. Hypoglycemia?
 - Check serum glucose; obtain sample before treatment
 - High clinical suspicion of hypoglycemia – give glucose before assessing fingerstick
2. Correct serum glucose:
 - Awake and cooperative patient – administer sugar-containing food or beverage PO. Sugar frosting can be administered sublingually
 - If patient is unable to take PO:
 - 25–75 g glucose as D50W (1–3 ampules) IV
 - Children: 0.5–1 g/kg glucose as D25W IV (2–4 ml/kg)
 - If unable to obtain IV access:
 - 1–2 mg glucagon IM or SC; may repeat every 20 minutes
 - Children: 0.025–0.1 mg/kg SC or IM; may repeat every 20 minutes

transiently. The patient's glucose concentration, as well as clinical status, should be monitored carefully after treatment. In a conscious patient that only required oral carbohydrate, one should monitor the patient for 1 hour before permitting the patient to leave the office. For the initially unresponsive patient, vital signs and blood glucose should be monitored at least every 5 minutes until medical assistance arrives. Many patients will require hospital admission for observation and continuous intravenous glucose infusion is often necessary.³⁸

Anaphylaxis

Any office that directly provides medications to patients, especially parenteral medications, needs to be prepared to deal with an anaphylactic reaction. Anaphylaxis is a true life-threatening medical emergency that is rarely anticipated. It accounts for 1500 deaths in the USA annually.³⁹ Anaphylaxis, a type I hypersensitivity reaction, results from binding of the offending antigen to preformed IgE antibodies on mast cells and basophils leading to systemic release of the immunologic mediators.

Presentation

The clinical presentation of anaphylaxis varies, but most often has cutaneous signs including urticaria and/or angioedema (Table 4.4). The presence of anaphylaxis is considered highly likely if any of the three criteria seen in Table 4.5 present within minutes to hours of administration of a medication.⁴⁰

Respiratory compromise and cardiovascular collapse are the usual cause of death in anaphylaxis.⁴¹

Table 4.4 Anaphylaxis: frequency of signs and symptoms. Adapted from: The diagnosis and management of anaphylaxis: an updated practice parameter. *J Allergy Clin Immunol* 2005;115(3 Suppl 2): S483–523.

Signs and symptoms	Frequency (%)
Cutaneous	90
Urticaria, angioedema	85–90
Flush	45–55
Pruritis, without rash	2–5
Respiratory	40–60
Upper airway edema	45–50
Dyspnea, wheeze	50–60
Rhinitis	15–20
Gastrointestinal symptoms: nausea, vomiting, diarrhea, crampy abdominal pain	25–30
Dizziness, syncope, hypotension	30–35
Other	
Headache	5–8
Susternal pain	4–6
Seizure	1–2

Up to 50% of the intravascular volume can shift to the extravascular space in a matter of 10 minutes leading to anaphylactic shock even before the onset of cutaneous findings.⁴²

The most common mediators of anaphylaxis encountered in the surgical practice include drugs, such as penicillin and aspirin (Table 4.6), and exposure to latex. The incidence of anaphylactic reactions to latex during medical procedures has increased over the last decade and has been reported to account

Table 4.5 Clinical criteria for diagnosing anaphylaxis. Adapted from: Sampson HA, *et al.* Second symposium on the definition and management of anaphylaxis: summary report – Second National Institute of Allergy and Infectious Disease/ Food Allergy and Anaphylaxis Network symposium. *J Allergy Clin Immunol*, 2006; 117(2): 391–7.

Anaphylaxis is highly likely when any one of the following is present:

1. Acute onset of illness (minutes to hours) with involvement of the skin, mucosal tissue, or both (pruritis, generalized urticaria, flushing, and/or swollen lips, tongue, or uvula) AND AT LEAST ONE OF THE FOLLOWING:
 - Respiratory involvement – dyspnea, wheezing, stridor, reduced peak-expiratory flow, hypoxemia
 - Hypotension or evidence of end-organ dysfunction – hypotonia, syncope, incontinence
2. Two or more of the following symptoms occurring rapidly (minutes to several hours) after exposure to a likely allergen for that patient:
 - Skin or mucosal involvement (pruritis, generalized urticaria, flushing, and/or swollen lips, tongue, or uvula)
 - Respiratory involvement – dyspnea, wheezing, stridor, reduced peak-expiratory flow, hypoxemia
 - Hypotension or evidence of end-organ dysfunction – hypotonia, syncope, incontinence
 - Gastrointestinal symptoms – crampy abdominal pain, vomiting
3. Hypotension after exposure to a known allergen for that patient within minutes to several hours:
 - Adults – systolic blood pressure less than 90 mmHg or 30% less than baseline
 - Infants and children – age-specific low systolic blood pressure or greater than 30% decrease in systolic blood pressure
 - 1 month to 1 year: less than 70 mmHg
 - 1–10 years: less than (70 mmHg + (2 × age))
 - 11–17 years: less than 90 mmHg

Table 4.6 Medications and anaphylaxis. Adapted from: Neugut AI, Ghatak AT, Miller RL. Anaphylaxis in the United States: an investigation into its epidemiology. *Arch Intern Med* 2001; 161(1): 15–21.

Antibiotics	Miscellaneous
Penicillin and derivatives	Aspirin
Cephalosporins	Non-steroidal anti-inflammatory drugs
Sulfonamides	Insulin
Tetracycline	Heparin
Ciprofloxacin	Protamine sulfate
Chloramphenicol	Immune globulin
Nitrofurantoin	Opiates
Vancomycin	Dextran
	Local anesthetics (esters)
	Glucocorticoids

for up to 27% of anaphylactic reactions occurring during general anesthesia.⁴³

Differential diagnosis

As the clinical presentation is variable, several disorders can share features with anaphylaxis. Vasodepressor syncope shares many features and should be considered in the differential diagnoses. However, with syncope, urticaria is absent, the patient is typically bradycardic rather than tachycardic, and respiratory symptoms are usually absent. Also, with syncope, the skin is typically cool and pale rather than flushed due to the vasodilation of anaphylaxis. Other diagnoses that can also cause abrupt and dramatic patient collapse include local anesthetic overdose, panic attack, cardiac arrest, foreign body aspiration, hypoglycemia, and seizure disorder.

Management

The initial signs and symptoms of allergy such as urticaria, erythema, pruritis, or wheezing may occur at any time after administration of a medication or local anesthetic. Allergic reactions occur as a continuum and can progress to the life-threatening respiratory or cardiovascular collapse very quickly.⁴⁴ The clinician should stop the procedure and be prepared for progression at any hint of allergy.

As with other emergencies, the airway, breathing, and circulation and level of consciousness should be assessed. In a suspected systemic allergy, however, administration of epinephrine should not be delayed. EMS should be alerted by a staff member. Every office emergency kit should include a preloaded syringe of epinephrine. It should be administered intramuscularly or subcutaneously as a 1:1000 dilution, 0.2–0.5 ml (0.2–0.5 mg) in adults, or 0.01 mg/kg in children usually into the lateral thigh, upper arm, or even intra- or sublingually.⁸ Gently massaging the site of administration may facilitate absorption. The dose may be repeated every 5 minutes as clinically indicated.

The patient should be placed in the Trendelenberg position to maximize cerebral blood flow. Establish and maintain an airway through head tilt, jaw thrust, or placement of an oral or nasal airway and provide supplemental oxygen. Laryngeal edema may also occur during an anaphylactic reaction and may occlude the airway, necessitating emergency cricothyroidotomy at any time during the management of the patient. Continuously monitor the patient's oxygen saturation, blood pressure and heart rate. Intravenous access should be obtained and 2 l of normal saline should be administered to adults and 20 ml/kg for children.

Once clinical improvement is seen after epinephrine and fluid are administered, other treatments can be administered. Antihistamines can dramatically improve symptoms of an allergic response but should

never be administered alone in anaphylaxis. Diphenhydramine can be administered intramuscularly or intravenously at 1–2 mg/kg up to 50 mg. Also, albuterol can be administered for continued bronchospasm. Corticosteroids are indicated to prevent recurrent or protracted anaphylaxis and can be administered by the surgeon or upon arrival at the emergency department. There is no established dose or dosage of choice, however hydrocortisone 5 mg/kg up to 250 mg has been recommended.⁴⁴

All patients with anaphylaxis should be taken to an emergency department for monitoring and observation as anaphylaxis can recur and present biphasically.⁴⁵

Seizures

Seizures are often perceived to the lay-person as a life-threatening emergency. However, seizures in isolation can be harmless as long as proper care is taken to prevent injury to the patient. They are the result of excessive activation of neurons in either the cerebral cortex or deep limbic system causing abnormal neurologic functioning.⁴⁶ Approximately 6% of the US population experience at least one afebrile seizure during their lifetime and this rate is considered to be higher in developing countries.⁴⁶

Seizures are classified into partial and generalized seizures. Partial seizures are restricted to discrete regions of the cerebral cortex. These are further classified into simple partial, if consciousness is maintained, and complex partial, if consciousness is lost. Generalized seizures result from activity in both cerebral hemispheres. These include absence, myoclonic, and the grand mal seizure or tonic-clonic seizure, the most common form of seizure disorder. Seizures can also be classified as primary or secondary. Secondary seizures are the result of an injury or illness affecting the central nervous system. Examples include traumatic brain injury, metabolic disturbances, tumors and infections of the nervous system.^{47,48} Seizures that have no known etiology are known as primary seizures.

Management

If a patient develops seizure-like activity in the office, the first thing to do is to confirm that it is actually a seizure. Syncope can be followed by abnormal movements resembling ictal activity. These movements, however, are usually brief and less forceful than tonic-clonic activity.

Patients who develop an aura or any sort of ictal activity should be reclined to the supine position or placed on the floor if not in the surgical chair, to minimize injury. Consideration to calling EMS should be made based on the history of the patient. As the patient is seizing, the surgeon should institute basic life support. The airway should be cleared of any

objects and a chin lift can help open the airway. The oral cavity can be suctioned with a soft suction catheter to prevent facial injury. A nasopharyngeal airway is preferred over an oropharyngeal airway as it can induce vomiting. A pulse should be checked to ensure that the convulsions are not secondary to cerebral hypoxia due to hypoperfusion. Oxygen should be administered and oxygen saturation monitored. Any objects near the patient should be moved by a member of the team to prevent injury. In most cases of tonic-clonic seizure activity, the duration is often less than 2 minutes and does not require administration of anticonvulsants. One must, however, continue to manage the generalized depression of the cardiovascular and respiratory systems in the postictal phase through close monitoring of vital signs and basic life support principles. A brief and limited seizure is easily managed and discharge home is based on whether this patient has a known seizure disorder or if this represents a new seizure. A first seizure should always be referred to the emergency department for consideration of inpatient work-up.

Status epilepticus

The true office life-threatening emergency is the patient who continues seizing and develops status epilepticus. Definitions vary, but it refers to seizures that last longer than 5–10 minutes or frequent seizures without return to baseline status between ictal states. The incidence in epileptic patients is around 5% and most likely results from failure of the patient to take anti-epileptic medications.⁴⁹ EMS should be called immediately if one suspects that the seizure is at all unremitting.

While continuing basic life support, one must rule out underlying, correctable causes of seizure activity. Attempts should be made to secure intravenous access if not already obtained. Hypoglycemia is a common cause of seizure activity and an ampule of 50% dextrose should be administered IV to rule out low blood glucose as a cause.

The first-line drugs for aborting seizure activity of all patients are benzodiazepines. Lorazepam 0.02–0.03 mg/kg should be administered IV.⁵⁰ One should allow a minute to assess effect. Diazepam 0.1 mg/kg IV or midazolam 0.05 mg/kg IV may be substituted if lorazepam is not available. If seizures continue after an initial dose, additional doses of lorazepam should be given at a maximum rate of 2 mg/min up to a total of 20 mg (0.1 mg/kg). If intravenous access cannot be achieved, diazepam can be given rectally (0.5–1.0 mg/kg), endotracheally, or intraosseously (0.2–0.5 mg/kg).⁵¹ Also, midazolam can be given intramuscularly (0.2 mg/kg).

If benzodiazepines do not terminate the seizure, the airway should be re-evaluated and intubation performed, particularly if the patient develops hypoxemia. Second-line agents should be administered, including phenytoin or its prodrug, phospho-

nytoin. Phenytoin is administered at 20 mg/kg as an infusion of 25–50 mg/min, and vitals signs should be monitored closely due to its hypotensive effects.⁵² Phosphenytoin causes much less hypotension, but is more expensive and should be administered at 15–20 mg/kg as an infusion of 100–150 mg/min. Both of these drugs can also be given intramuscularly.⁵³ Refractory status epilepticus after giving these drugs indicates a grave prognosis and any further management requires an intensive care setting. The practitioner must continue to closely monitor the patient and administer basic life support while awaiting EMS.

Seizures can and do happen in both epileptic and non-epileptic patients. All practicing oral and maxillofacial surgeons should be prepared to deal with them at any time.

Chapter 5

Local Anesthesia

John Gerard Meechan

This chapter explains the current understanding of the mechanism of action of local anesthetics. It describes the techniques and materials that are used for local anesthesia in and around the jaws. In addition the localized and systemic adverse effects of local anesthesia in this region are considered.

Introduction, 51

Mode of action of local anesthetics, 51

Techniques of local anesthesia for oral and maxillofacial surgery, 52

Topical anesthesia, 52

Infiltration anesthesia, 52

Regional block anesthesia, 52

Supplementary intraoral techniques of local anesthesia, 56

Local anesthetic drugs, 57

Lidocaine, 57

Mepivacaine, 57

Prilocaine, 57

surgery. It may be the sole method of pain control, used in combination with sedation, or as a supplementary technique in conjunction with general anesthesia. A number of different techniques and drugs are available for use in and around the jaws and these are described below.

Mode of action of local anesthetics

Local anesthetic drugs achieve their action at the voltage-gated sodium channel. In simple terms they inhibit sodium entry into nerve cells. As the entry of sodium into the nerve cell during the firing cycle is the chief driver producing depolarization, blockade of sodium transfer causes inhibition of neural activity.

Knowledge of the structure of the sodium channel is essential for an understanding of the action of local anesthetics. The structure of the sodium channel has been well characterized.¹ It is composed of three subunits known as alpha, beta₁ and beta₂. The pore through which sodium enters is contained in the alpha subunit and a diagrammatic representation of this component is shown in Fig. 5.1. The alpha subunit is made up of four similar domains (I–IV) each of which contains six protein segments (S1–S6). At rest the positively charged S4 projects into the channel preventing sodium entry. During depolarization S4 moves away from the pore in a movement called the

Introduction

Local anesthesia is an important method of pain control for many procedures in oral and maxillofacial

Fig. 5.1 The alpha subunit of the sodium channel: (a) in the resting state with S4 segments in the body of the channel; (b) in the firing configuration with S4 segments in wall of the channel; (c) in the refractory orientation with a protein loop extended into the channel; (d) exposure of binding site for local anesthetics in segment S6; (e) binding of local anesthetic maintaining refractory orientation.

sliding helix. This maneuver opens up the channel, permitting sodium entry. During the refractory period a protein link between domains III and IV projects into the channel producing a new blockade to sodium entry. When it projects into the channel this loop exposes a site on segment 6 of domain IV to which local anesthetics bind.² The binding of the local anesthetic then maintains the loop in its blocking position.

It should be pointed out that the sodium channel is not a singular structure and that at least nine different variations have been identified.³ In theory this means that very selective local anesthetics could be developed. At present the local anesthetics used clinically are not specific for peripheral sensory nerves and can affect transmission in any excitable tissue such as motor nerves, central nervous, and cardiovascular tissue. This means they are capable of producing unwanted effects and these are discussed later.

Techniques of local anesthesia for oral and maxillofacial surgery

There are a number of different techniques that can provide local anesthesia in and around the mouth and jaws. These include methods that are used elsewhere in the body such as topical anesthesia, infiltration, and regional block techniques; however there are methods that are unique to the mouth and jaws such as intraosseous, intraligamentary, and intrapulpal injections.

Topical anesthesia

Topical anesthesia can be useful when applied to the oral mucosa. It may be employed prior to local anesthetic injections in the mouth to lessen the discomfort of needle penetration. This can be effective prior to infiltration anesthesia when the topical agent has been placed on reflected mucosa; however application to keratinized tissue such as palatal mucosa is not so useful and there is no evidence that topical application lessens the discomfort of regional block techniques.

Topical anesthetics for intraoral use are available in a number of formulations including creams, ointments and sprays. The local anesthetic agents most commonly used as topical anesthetics in the mouth are lidocaine and benzocaine. Oraqix[®] is a combination of lidocaine and prilocaine specifically designed for intraoral topical anesthesia.

Advances in topical anesthesia (for example the development of Oraqix[®] and incorporation of drugs into liposomes) have meant that some intraoral soft tissue procedures can be performed using topical anesthesia as the sole agent; however anesthesia of the teeth and jaws is not at present possible by this method.

Infiltration anesthesia

Infiltration anesthesia is useful in providing localized skin and mucosal anesthesia and can also be used to provide anesthesia for some teeth and part of the jaws. It is the technique of choice in the maxilla for dental pulpal anesthesia and can also be used for this purpose in the mandible of children for anesthesia of the deciduous dentition. It can be successful in the incisor teeth in the adult mandible and there is increasing evidence that some formulations (see below) can be effective when infiltrated in the molar region of the mandible.

When used intraorally, access to the point of needle penetration is easiest when the patient has the mouth only partly open. The technique is performed by inserting the needle through reflected mucosa at the depth of the buccal sulcus; if bone is contacted the needle should be withdrawn slightly so that it is supraperiosteal. A supraperiosteal location is recommended as injection below the periosteum is painful at the time of injection and may cause postinjection discomfort. Following aspiration 1.0–2.0 ml of solution is deposited at a rate of 30 s/ml. This rate is slower than many practitioners use. Slow injection has a number of advantages. It reduces discomfort and increases success. In addition a slow rate of injection may lessen the effects of systemic problems (see below).

This method allows about 45 minutes of anesthesia of the dental pulps when a solution containing a vasoconstrictor (such as lidocaine with epinephrine) is used; soft tissue anesthesia is longer and the patient may have subjective anesthesia of the soft tissues for 1.5–2 hours.

Regional block anesthesia

Several regional block techniques are described to anesthetize structures in the jaws.

Mandibular anesthesia

There are a number of methods used to anesthetize the lower jaw, teeth and associated structures and these are discussed below. It should be remembered that midline structures (such as lower central incisor teeth) often receive bilateral supply; therefore these may not be satisfactorily anesthetized by a single regional nerve block.

Inferior alveolar nerve block (Halstead technique)

This method anesthetizes the teeth and bone on one side of the mandible along with the soft tissues on the buccal aspect anterior to the mental foramen. The Halstead method achieves its effect by deposition of the solution in the pterygo-temporal space on the medial aspect of the mandibular ramus, specifically in the region of the mandibular foramen. When successful this technique anesthetizes the inferior

alveolar nerve, which supplies the teeth on the same side of the mandible, the bone of the mandible to the midline and the soft tissues of the lower lip to the midline as well as the reflected and attached gingivae from the premolar teeth to the midline. In addition this injection usually anesthetizes the lingual nerve that supplies the anterior two thirds of the tongue on one side.

The technique is illustrated in Fig. 5.2. The patient has the mouth open wide and the operator places the thumb of the non-syringe hand in the mouth on the coronoid notch of the mandible; the index finger is extraoral at the same height on the posterior border of the ramus. The syringe is advanced to the point of needle penetration across the lower premolar teeth of the opposite side. The point of penetration of the needle is between the internal oblique ridge of the mandible (which was palpated by the operator's thumb before resting on the coronoid notch) and the pterygomandibular raphe (which is visible). The height of needle penetration is halfway up the operator's thumb nail. A long 35mm needle no narrower than 27 gauge is used and advanced until bone is contacted; this is usually around 25mm of needle insertion. After contacting bone the needle is withdrawn slightly, aspiration performed and 1.5–2.0ml of solution deposited slowly.

Two common problems with this method are either contacting bone too soon (after 5–10mm of insertion) or failure to touch bone. The former is corrected by withdrawing the needle away from the bone, but not completely out of mucosa, and swinging the barrel of the syringe over the mandibular teeth of the side being anesthetized. The needle is

then advanced about 25mm and swung back again over the opposite premolar teeth; the rest of the injection is completed as described above. This is a modification of the indirect method of performing an inferior alveolar nerve block. If bone is not contacted after about 30mm of insertion the needle should be withdrawn until about 15mm is still in tissue and the syringe swung over the molar teeth of the side not being injected and then advanced until bone is contacted. Failure to contact bone may lead to injection into the parotid gland, leading to hemifacial paresis (see below).

When a vasoconstrictor solution such as lidocaine with epinephrine is used this technique will anesthetize the hard tissues including the teeth for around 45 minutes; however subjective soft tissue numbness may be apparent for up to 3 hours. When the so-called long-acting solutions are employed anesthesia of the teeth can last for 6–8 hours.

Gow-Gates technique

In addition to the anesthesia of the inferior alveolar nerve this method⁴ may anesthetize the lingual, long buccal, mylohyoid and auriculotemporal nerves. This may be of value in countering accessory nerve supply to the teeth and jaw. This approach deposits solution more superiorly than the Halstead technique and that is the reason why more branches of the mandibular nerve are affected by this injection. The target is the mandibular condyle (Fig. 5.3). As with the Halstead approach the patient has the mouth open wide. The syringe is advanced in a plane parallel to a line visualized between the corner of the mouth and the inter-tragal notch. The syringe, fitted with a long needle, is introduced into the mouth across the maxillary canine tooth of the opposite side to that being injected and advanced across the palatal cusps of the maxillary second molar on the injected side. The needle is advanced in this direction until the bone of the condyle is contacted, withdrawn slightly and, after aspiration, 2.0ml of solution is deposited. The patient should maintain their mouth in the open position for as long as possible after injection. This method appears to be more successful in anesthetizing teeth than the Halstead approach. This may be the result of combating nerves other than the inferior alveolar nerve that might supply the teeth.

Akinosi Vazirani technique

This technique⁵ also anesthetizes the lingual and mylohyoid nerves and on occasion the long buccal nerve. This technique (Fig. 5.4) differs from the methods described above in two respects. Firstly, it is administered with the patient's mouth closed and so is useful in individuals who cannot fully open their mouth and is helpful in individuals with large or uncontrollable tongues when it is difficult to get access to the insertion point of a Halstead block. Secondly, there is no bony end-point for needle insertion. As is normal for all of the methods used to anesthetize the mandibular nerve, a long needle no narrower than 27 gauge is required. The syringe is introduced intraorally in the buccal sulcus along a plane level with the mucogingival junction of the maxillary mucosa. It is advanced at this level towards the posterior aspect of the maxilla until the hub of the needle is adjacent to the distal surface of the maxillary second molar. At this point the needle will have entered the mucosa and reached the correct depth of insertion. Aspiration is performed and 2.0ml of solution injected slowly. If the anterior aspect of the mandibular ramus is contacted the barrel of the syringe can be swung more laterally or the patient instructed to move their lower jaw over to the side being injected. This method anesthetizes the inferior alveolar nerve, lingual nerve, nerve to mylohyoid, and occasionally the long buccal nerve.

Mental and incisive nerve block

This injection anesthetizes the teeth and jaw from the premolars anteriorly as well as the soft tissues of the lower lip and chin to the midline on one side. Anesthesia of the first molar tooth is achieved in some cases. It relies on the deposition of solution around the mental nerve as it exits the mental foramen and the entry of solution into the foramen to block the incisive branch that supplies the lower anterior teeth on the same side. The usual method is intraoral although an extraoral approach may also be used. The needle is inserted at the depth of the buccal sulcus between the premolar teeth and advanced to a zone below the premolar apices. Around 1.5ml of solution should be deposited and after injection the tissues should be massaged to encourage entry of solution into the mental foramen.

Fig. 5.4 The position of the syringe for the Akinosi-Vazirani mandibular block. Reproduced with permission, © Quintessence Publishing Co Ltd.

Long buccal nerve block

If the long buccal nerve has not been anesthetized by the methods used above (for example if the Halstead technique was used) then this nerve must be anesthetized separately if required. The area supplied is the buccal gingivae and mucosa and part of the cheek in the mandibular molar region. The nerve can be anesthetized by either buccal infiltration in the zone of interest or by a regional block. The regional block is achieved by depositing 0.5ml of solution in the region of the coronoid notch of the mandible (the point at which the thumb rests during the Halstead technique).

Extraoral approach to the mandibular nerve

The techniques described above rely upon intraoral approaches to the branches of the mandibular nerve, although it was mentioned that the mental nerve may be blocked from outside of the mouth. It is possible to anesthetize the mandibular nerve using an extraoral method.

This technique approaches the foramen ovale via the sigmoid notch of the mandibular ramus. The site of insertion is the most concave point of the lower border of the zygomatic arch. A long needle is introduced at 90° to the skin and the sagittal plane and maintains contact with the lower border of the zygomatic arch. The needle is advanced until the bone of the lateral pterygoid plate is contacted. The depth of insertion of the needle at the point of bony contact is noted. This is important as it establishes the correct depth for the final injection. The needle is now withdrawn almost fully but leaving the tip under the skin. It is then redirected at an angle of 60° to the sagittal plane and advanced and this time will pass just behind the pterygoid plates. The final position for deposition of solution is no more than 4mm deeper than that established with the initial penetration to the pterygoid plates.

Maxillary anesthesia

Several regional block techniques are used in the maxilla. These are described below.

Maxillary nerve block

There are intraoral and extraoral approaches to the maxillary nerve block. The intraoral methods are the

tuberosity approach and the greater palatine foramen approach. The maxillary nerve block anesthetizes the teeth and bone of the maxilla on one side together with the buccal and palatal mucosa, the skin and mucosa of the upper lip, the lower eyelid, and the lateral aspect of the nose.

Tuberosity approach

This is administered by depositing solution high in the buccal sulcus in the plane of the distal surface of the maxillary second molar tooth. The needle is advanced at an angle of 45° superiorly, posteriorly and medially to a depth of 30mm, at which point 2.0ml of solution is deposited following aspiration.

Greater palatine foramen approach

This technique involves inserting a needle into the pterygopalatine fossa via the greater palatine foramen. The patient has the mouth open wide and the greater palatine foramen is identified as a depression medial to the distal surface of the second maxillary molar tooth. The needle is inserted into the greater palatine foramen and advanced at an angle of 45° superiorly and posteriorly to a depth of 30mm. At this point 2.0ml of solution is deposited.

Extraoral approach

This is similar to that described above for the extraoral approach to the foramen ovale. This time the target is the foramen rotundum. The point of insertion is identical to that described for the extraoral mandibular nerve block. Similarly, the needle is advanced until the lateral pterygoid plate is contacted. The depth of insertion is noted. The needle is withdrawn and redirected towards the pterygopalatine fossa. This is achieved by pointing the needle 10° more superiorly and 15° more anteriorly until the depth of insertion determined by the original needle insertion is reached. This is the point of delivery of solution.

Posterior superior alveolar nerve block

This injection anesthetizes the maxillary molar teeth, associated bone and buccal gingivae. In those individuals with a middle superior alveolar nerve the first molar will not be satisfactorily anesthetized with this method as the mesiobuccal root of this tooth is supplied by that nerve (see below). The technique is identical to that described for the tuberosity approach to the maxillary nerve except that needle penetration is only 20mm.

Maxillary molar nerve block

This is an adaptation of the posterior superior alveolar nerve block.⁶ It is designed to anesthetize the maxillary molar teeth by countering any accessory supply to the mesio-buccal pulp of the first molar from the middle superior alveolar nerve. During the injection the patient has the mouth half closed. The operator's finger palpates the zygomatic process of the maxilla intraorally and advances the finger poste-

riorly towards the maxillary tuberosity. The needle penetrates mucosa high in the buccal sulcus between the finger and the distal surface of the zygomatic process and advanced about 10mm into the space above the buccinator attachment. At this point aspiration is performed and 2.0ml of local anesthetic solution is injected. Finger pressure is maintained throughout the injection. Following injection the patient is asked to close the mouth slightly and the solution, which has created a swelling above the buccinator, is massaged in a superior, medial and distal direction towards the posterior superior alveolar foramen.

Middle superior alveolar nerve block

This injection anesthetizes the premolar pulps as well as the mesio-buccal pulp of the maxillary first permanent molar tooth. The technique is performed by delivering a buccal infiltration at the apex of the second premolar tooth.

Anterior superior alveolar nerve block

The anterior superior alveolar nerve supplies the maxillary incisor and canine teeth on one side of the jaw. It can be anesthetized either by an infraorbital nerve block (described below) or by a buccal infiltration in the region of the apex of the canine.

Infraorbital nerve block

The infraorbital nerve can be approached either from the intraoral or the extraoral sides. The intraoral approach (Fig. 5.5) involves inserting a long needle high into the buccal sulcus between the premolar teeth and advancing towards the infraorbital foramen, which is being palpated extraorally by the operator's non-syringe hand. At this point 1–1.5ml of solution is deposited following aspiration.

This injection anesthetizes the teeth and associated bone from the second premolar to the central incisor (although the latter may obtain some collateral supply from the opposite side). In addition the gingivae adjacent to these teeth and the mucosal and skin surfaces of one half of the upper lip and part of the skin on the lateral aspect of the nose are affected.

Greater palatine nerve block

This method anesthetizes the soft tissues of the palate from the foramen anteriorly to the canine region. The nerve can be anesthetized at any point by a palatal

Fig. 5.5 The intraoral approach to the infraorbital nerve block. Reproduced with permission, © Quintessence Publishing Co Ltd.

infiltration; however the true block involves injection of 0.5 ml of solution in the region of the greater palatine foramen. The soft tissues of the hard palate up to the canine region on one side will be anesthetized. In addition this technique can be effective in countering any palatal supply to the maxillary teeth. Duration of anesthesia is not as long as with mandibular blocks. Indeed both palatal infiltration and blocks provide a similar duration of around 45 minutes of soft tissue anesthesia.

Nasopalatine nerve block

This method anesthetizes the tissues of the hard palate adjacent to the incisor teeth bilaterally. It is performed by injecting 0.2–0.5 ml of solution adjacent to the incisive papilla.

Anterior middle superior alveolar nerve block

This technique relies on the slow delivery of solution and is best achieved using a computer-controlled local anesthetic delivery device.⁷ The method works by entry of local anesthetic solution into the cancellous bone of the maxilla via multiple foramina in the hard palate. It anesthetizes the soft tissues of the palate and the teeth from the premolars anteriorly on one side. The needle is inserted halfway between the palatal midline and the premolar palatal gingival margin and 1.0 ml of solution is injected very slowly.

Palatal anterior superior alveolar nerve block

This technique achieves anesthesia of the teeth and anterior hard palate mucosa by the deposition of around 1.0 ml of local anesthetic solution into the nasopalatine foramen and thence into the cancellous bone of the anterior maxilla.⁸ As was the case with the anterior middle superior alveolar nerve block injection, the technique is most readily achieved using a computerized local anesthetic delivery device as a slow rate of delivery is required for patient tolerance. This technique can achieve pulpal anesthesia of the canine and incisor teeth bilaterally and on occasion may also anesthetize the premolar teeth.

Supplementary intraoral techniques of local anesthesia

Intraosseous anesthesia

This method (Fig. 5.6) can be used in either jaw and, although it can be employed as a primary technique, it is normally reserved as a supplementary injection when conventional measures fail to produce adequate anesthesia of the pulps of teeth. The method is as follows. Firstly the buccal gingiva around the tooth of interest is anesthetized by a small-dose (0.2–0.5 ml) buccal infiltration. A perforation through soft tissue and cortical bone is made using a perforator matched to the needle (these are provided in customized systems) or with a small round dental bur. The point of penetration is 2 mm below the intersection of two

imaginary lines. These are: a line joining the lowest part of the buccal gingival margin of the tooth of interest and its posterior neighbour; and a line at 90° to the former line that bisects the interdental papilla. If the point 2 mm below the intersection of these two lines is in reflected mucosa a point more coronal in attached gingiva is chosen. Once the perforation has reached cancellous bone the perforator or bur is replaced with a needle and 1.0 ml of solution injected slowly intraosseously. As intraosseous deposition of solution is equivalent to intravenous entry, slow deposition and dose limitation are important with this technique.

Intraligamentary (periodontal ligament) anesthesia

This is regarded as a specific version of an intraosseous technique (Fig. 5.7). Like the method described above it can be used as a primary method of anesthesia but it is considered a supplementary method when tooth pulpal anesthesia is problematic. There are specialized syringes designed specifically for this method; however it is equally effective with conventional delivery systems. Normally a 30 gauge needle is used. It is inserted to the point of maximum pene-

Fig. 5.7 The intraligamentary injection. Reproduced with permission, © Quintessence Publishing Co Ltd.

tration at the mesio-buccal aspect of the root of the tooth (each root for a multirooted tooth). The needle becomes wedged at the crest of the interdental bone and will not traverse far into the periodontal space. Delivery of solution (0.2ml per root) is performed slowly with controlled pressure. The method obtains anesthesia by entry of the local anesthetic solution into the cancellous space of the bone via the perforations in the cribriform plate of the socket. As the number of these perforations is low in anterior mandibular sockets the technique is not very successful in lower incisor teeth.

Intrapulpal anesthesia

This method (Fig. 5.8) has limited indications, as exposure of the tooth pulp is essential. It is unique among the techniques described here as the presence of a local anesthetic solution is not essential for success: saline has been shown to be as effective.⁹ The key to success is delivery of solution under pressure. This can be achieved with a needle that fits tightly into the pulpal exposure, by advancement of the needle into the pulp canal until it is wedged or by placing an obturator such as a cotton wool bud around the needle during injection. This is the most localized form of anesthesia described here and in theory could be used to anesthetize one pulp canal of a multirooted tooth.

Local anesthetic drugs

Various drugs are available for local anesthesia in and around the jaws. These can be classified in a number of ways. The main categorization is by chemical structure. Local anesthetics are divided into two groups by their composition. These are the esters and the amides. The local anesthetics in current use as injectable agents are amides. The ester procaine is only used in those patients who are proven to be allergic to amides and such cases are very rare. Topical anesthetics such as benzocaine and tetracaine (amethocaine) are esters. There are two major differences between esters and amides; these relate to metabolism and the production of allergy. Esters are

Fig. 5.8 An intrapulpal injection in a molar tooth. Reproduced with permission, © Quintessence Publishing Co Ltd.

metabolized in plasma. Most amides primarily undergo hepatic metabolism, although prilocaine also undergoes some breakdown in the lungs. Articaine is an exception: although it is an amide, its primary metabolism occurs in the plasma.

In addition to categorizing local anesthetics by their chemical structure they can also be classified with respect to their duration of action into conventional and long-acting agents. Conventional agents may provide better operative anesthesia; however long-acting agents may be preferred for postoperative pain control, especially in combination with general anesthesia. In order to achieve their long-acting effect such agents must be employed as regional blocks.

Lidocaine

Lidocaine is the gold standard drug to which all others are compared. When used as a plain solution in concentrations up to 2% it provides short-lasting soft tissue anesthesia. Such a formulation does not provide acceptable anesthesia of the dental pulps. When a vasoconstrictor is added to 2% lidocaine then satisfactory anesthesia is provided for the teeth. The vasoconstrictor most commonly employed is epinephrine (adrenaline) usually in the concentration range of 1:200 000 (5 µg/ml) to 1:80 000 (12.5 µg/ml).

Mepivacaine

Mepivacaine, when injected at a concentration of 2% in combination with 1:100 000 epinephrine, provides similar anesthesia to 2% lidocaine with epinephrine. It is also provided as a plain 3% solution and this provides better anesthesia than 2% lidocaine when a vasoconstrictor-free solution is required.

Prilocaine

Prilocaine is used as a plain 4% solution or as a 3% formulation in combination with the vasoconstrictor felypressin (a synthetic analog of vasopressin). The 3% formulation is a useful alternative to 2% lidocaine with epinephrine if an epinephrine-free solution is indicated.

Articaine

As mentioned earlier articaine is unique among the amides in that initial metabolism occurs in plasma and thus, having a shorter plasma half-life, it is safer systemically than the other amides. This means that it can be used in higher concentration and so most articaine formulations are 4% with epinephrine in either 1:100 000 or 1:200 000 concentrations. There are some concerns, however, that local anesthetic drugs used in high concentration may increase the chances of localized toxicity leading to long-lasting anesthesia, paraesthesia or dysaesthesia when used for regional

blocks (see later). An advantage of the 4% articaine solution is that it is superior to 2% lidocaine solutions in providing anesthesia of the mandibular teeth following infiltration in the adult mandible.¹⁰ There is some evidence that buccal infiltration with 4% articaine is as effective as inferior alveolar nerve blockade with 2% lidocaine in providing anesthesia of the adult mandibular teeth.¹¹

Etidocaine

Etidocaine in a concentration of 1.5% with 1:200 000 epinephrine has been used in oral surgery. It has a longer duration of action than 2% lidocaine with epinephrine 1:100 000 when used as a regional block but is not as effective as lidocaine with epinephrine when used for infiltration anesthesia.¹²

Bupivacaine

Bupivacaine is a long-lasting local anesthetic. When used as a supplementary intraoral injection during general anesthesia this drug has been shown to reduce the number of analgesics required for postoperative pain control following oral surgery.¹³ It is presented in a number of formulations ranging from 0.25–0.75% with and without epinephrine (usually 1:200 000).

Levobupivacaine

This is a single isomer of bupivacaine and has the advantage of being less cardiotoxic. It has been shown to be as effective a local anesthetic as bupivacaine and, like the latter drug, its use as an intraoral injection during general anesthesia can reduce postoperative analgesic requirements following oral surgery. It is available in concentrations ranging from 0.25–0.75%.

Ropivacaine

Like levobupivacaine this is a single isomer with reduced cardiotoxicity compared to bupivacaine. There is a suggestion that it may be as effective with and without a vasoconstrictor; when used intraorally, however, the presence of epinephrine increases efficacy.¹⁴ It is available in concentrations ranging from 0.2–1.0%

Complications of local anesthesia in the orofacial region

In addition to failure of local anesthesia there are a number of complications that can occur following the use of local anesthetics in the orofacial region. These can be separated into localized and systemic complications.

Localized complications

Localized complications can arise either as a result of physical damage from the needle or chemically as a result of the local anesthetic.

Nerve damage

Nerve damage can occur following regional block techniques. The nerve that is most commonly affected is the lingual nerve. This can be due to physical trauma from the needle, which can result in altered sensation lasting for a few weeks. Normal sensation should recover in most cases following such trauma. The deposition of local anesthetic into the nerve bundle should be avoided as this can cause damage, both as a result of the physical disruption and chemically.

As mentioned above, the concentration of the local anesthetic has been implicated in the production of long-lasting paresthesias. Certainly *in vitro* the survival of nerve cells decreases as the local anesthetic concentration rises.¹⁵ There is some circumstantial evidence from both North America¹⁶ and Europe¹⁷ that local anesthetics in the concentration of 4% are associated with more paresthesias (particularly of the lingual nerve) than 2% and 3% solutions, although other investigations have failed to confirm this.¹⁸

If nerve function does not return to normal within a few weeks the prognosis is poor. Unfortunately surgical repair is not as effective compared to the treatment of surgically damaged nerves.¹⁹

Motor nerve paralysis

Local anesthetics are not specific for peripheral sensory nerves and motor function can be affected. Facial nerve function may be affected if solution is injected into the substance of the parotid gland. Fortunately any paralysis produced is temporary. This may occur during the delivery of mandibular block techniques but can be avoided when using the Halstead method if bone is palpated before solution is delivered. This should ensure that the needle is not advanced beyond the posterior border of the mandibular ramus. The most serious consequence is loss of the blink reflex and thus the patient must have some form of eye protection until the effect wears off.

Trismus

Mandibular block techniques involve deep penetration of the needle and this may cause minor bleeding. If this occurs in the medial pterygoid muscle it can lead to muscle spasm and the inability to fully open the mouth. Although this problem does resolve it may take a few weeks to do so.

Intravascular injection

Intravascular injection can cause both localized and systemic (see below) complications. The use of an

aspirating technique should reduce the chances of intravascular injection. Localized problems may result from intra-arterial injection. It is more difficult to penetrate an artery compared to a vein, however it is not impossible and a variety of adverse effects may ensue. Entry or contact of an artery is painful and arteriospasm may produce localized vascular shut-down, which appears as blanching. Injecting local anesthetic into an artery that has an intracranial course can result in a number of spectacular sequelae. Vision may be affected. Both diplopia and loss of vision have been recorded following intraoral injections. Hearing loss has also been noted. The most dramatic effect reported is hemiparesis. This could result from the phenomenon known as reverse carotid flow. This occurs when local anesthetic is injected into a branch of the external carotid artery under pressure. This can send some of the agent to the carotid bifurcation resulting in transport of some anesthetic intracranially via the internal carotid. Such an effect has been demonstrated in animals following injection into the facial artery. This rare complication can be reduced by aspirating and injecting slowly.

Systemic complications

The following systemic complications caused by the injected agent can occur after the injection of local anesthetics: allergy, infection, toxicity, and drug interactions. These are discussed below. Other systemic complications such as syncope are unrelated to the injected solution.

Allergy

Allergic reaction to the amide group of local anesthetics is extremely rare. Many individuals who claim to be allergic are found not to be so after formal testing. Nevertheless any individual complaining of non-localized swelling, rash, or breathing difficulty following injection should be tested, as the full range of allergic reactions, including anaphylaxis, has been reported after intraoral injections. Ester allergy is more common. Some local anesthetic cartridges (carpules) contain latex in their plungers or diaphragms and these should be avoided in patients with severe latex allergy. Older local anesthetic formulations contained preservatives related to paraben and this could cause allergic reactions in susceptible patients; however most modern formulations are preservative-free.

Infection

Sensible precautions are essential during the administration of local anesthesia to prevent contaminating the patient and to avoid transfer of infection between operator and patient. The use of safety-type syringes, which eliminate resheathing of used needles, has

been shown to reduce the chances of needle-stick injury. The use of such equipment is recommended.

Toxicity

As many local anesthetics contain an anesthetic and a vasoconstrictor it is, in theory, possible to have a toxic reaction to either component; however as a result of their relative concentrations, a patient is more likely to suffer a toxic reaction to the anesthetic. The systems most susceptible to toxicity are the central nervous and cardiovascular systems. Most serious cases of overdose are the result of central nervous system effects. A toxic reaction to the anesthetic initially manifests as overexcitation, such as excessive talking and tremors. The later stages are signs of central nervous system depression ultimately leading to unconsciousness, and fatality can result from respiratory depression. The management is to stop the injection, monitor vital signs, and provide basic life support.

Overdose of epinephrine presents as anxiety, headache, and palpitations. If this occurs the patient should be sat upright and administered oxygen.

Systemic toxicity from local anesthetics can be the result of intravascular injection, use of excessive doses, or inability of the patient to metabolize the drug. Intravascular injection should be avoided by use of an aspirating technique. This is essential. Some workers report positive aspirates in over 20% of mandibular block injections.

Overdose of local anesthesia can occur, particularly in children. The maximum dose is related to the patient weight. This means that overdose is more likely to occur in children. Table 5.1 gives the recommended maximum doses for healthy individuals for the local anesthetics discussed in this chapter.

Table 5.1 Maximum recommended doses for healthy individuals for local anesthetics.

Drug	Maximum recommended dose (mg/kg)
Lidocaine	4.4
Mepivacaine	4.4
Prilocaine	6.0
Articaine	7.0
Etidocaine	8.0
Bupivacaine	1.3
Levobupivacaine	1.3
Ropivacaine	1.5

Hepatic disease will reduce the metabolism of local anesthetics and this must be considered when deciding maximum doses for patients with such conditions.

Drug interactions

Interactions may occur between concurrent medication and local anesthetics or vasoconstrictors. There is

no concurrent medication that absolutely contraindicates the use of local anesthetics or vasoconstrictors; however there are times when a dose reduction is required. The main group of drugs that necessitate dose reduction are the cardiovascular drugs. In theory all antihypertensive medications can interact with epinephrine, for example beta-adrenergic blocking drugs can result in unopposed rises in systolic blood pressure, and calcium channel blockers and diuretics may increase epinephrine-induced hypokalaemia. Similarly beta-adrenergic blocking drugs can increase the toxicity of local anesthetics by reducing hepatic blood flow, which inhibits metabolism.

As well as prescribed medication, drugs of abuse such as cocaine can interact with epinephrine and avoidance or dose reduction of epinephrine-containing anesthetics is wise for patients who have recently used this drug.

Although there are no absolute contraindications to the use of particular local anesthetics resulting from drug interactions there are some medical conditions where the use of an epinephrine-containing solution should be avoided. These include unstable angina, severe cardiac dysrhythmias, untreated pheochromocytoma and untreated hyperthyroidism.

Chapter 6a

Sedation and General Anesthesia in Oral and Maxillofacial Surgery: A UK Perspective

C. Michael Hill

In the UK, the use of sedation and anesthesia in general practice (the dental office) has been severely restricted to light sedation with single-agent techniques on patients who are generally fit and well (ASA 1 and 2 only). All other patients are referred to a specialist setting, usually within a hospital environment, where they can be managed by trained sedationists or anesthesiologists. The technique of conscious sedation is defined as a state of depression of the central nervous system (CNS), allowing a cooperative patient with whom verbal communication can be maintained. Any drug used must carry a wide safety margin. The vast majority of UK sedation is focused on the benzodiazepines and, for inhalational sedation, on nitrous oxide. The use of other agents such as fentanyl and ketamine is rare.

History

The discovery of nitrous oxide by Joseph Priestley in 1776 and its subsequent use by Humphry Davy to alleviate toothache began a golden era of pain control and relief which the dental profession has exploited ever since. Despite this, and nearly 250 years later, the fear of visiting the dentist is still quoted in the UK as the most common reason why patients fail to visit their dentist on regular occasions.

Some 75 years after Priestley's discovery, Horace Wells of Hartford, Connecticut, gave the first public demonstration of the practical use of nitrous oxide. It was 10 December 1844 and, despite some ridiculing by the elitist medical profession of the day, is generally accepted as the birthdate of modern anesthesia and sedation. In truth, 2 years previously, Crawford Long had anesthetized James Venable and excised two small neck tumors. Unfortunately, he failed to publish his results until 1849 and so has never had the prominence of William Morton (see below) or Horace Wells.

As for Wells, he committed suicide 4 years after discovering anesthesia, incensed that his discovery had been "stolen" by William Morton (Fig. 6a.1). In reality, it seems that Morton was a master at adapting the ideas of others and in 1846, Professor Jackson, a specialist of chemistry, physics and geology, suggested the use of sulfuric ether as a possible volatile anesthetic agent rather than nitrous oxide. On 16 October 1846, Morton successfully anesthetized

Fig. 6a.1 William Morton demonstrating ether anesthesia.

Gilbert Abbott thereby allowing surgeon John Warren to remove a tumor from his patient. Unlike Wells, Morton received wide acclaim for his technique but his life on earth ended some 22 years later. He was virtually bankrupt, having lined the pockets of several lawyers and even fought in Congress for the patents and rights to be known as the inventor of anesthesia.

Over the next 50 years the use of ether, chloroform, and triethylene (trilene) developed slowly on both sides of the Atlantic. In the UK, the use of chloroform on Queen Victoria also saw the first recorded use of the term “specialist in anaesthesia”, applied to John Snow.

It is difficult to trace the precise developments of sedation and anesthesia at the end of the 19th century, but the advent of “daycase”, “outpatient” or “ambulatory care” anesthesia can probably be attributed to JH Nicholl who in 1909 published a series of just under 9000 cases treated at the Glasgow Royal Hospital for Sick Children.¹ In the USA, Ralph Waters opened a clinic in Sioux City, Iowa in 1916 expanding his facilities into Kansas City in 1925. These clinics are generally regarded as the forerunners of modern, stand-alone daycase units.

However, the main differences in the early days of anesthesia related to the assumption of responsibilities: in the UK it remained the responsibility of the medical and dental profession; in the USA (and in much of Europe) anesthesia was largely regarded as an adjunct to surgery and became a designated function of the nurses. Even so, on both sides of the Atlantic Ocean, the period around the 1920s saw some major advances in anesthesia with the formation of societies, the development of anesthetic machinery, and the advent of intravenous anesthetics and effective local and regional anesthesia. One of the earliest accounts is that of Douglas MacDonald who used a naturally occurring alkaloid (Somniferine) to “lightly” anesthetize a patient prior to a regional abdominal block.² This concept of “light anesthesia” appears to coincide with the work of John Lundy of the Mayo clinic who described a stage of sedation preceding anesthesia.³ Lundy developed the use of compounds of barbituric acid (in particular pentobarbitone) which became the cornerstone of intravenous anesthesia for the next 50 years. Barbituric acid had been formulated in the mid-1860s (a synthesis of urea and malonic acid) but it was its derivative compounds which continued to fuel the development of modern anesthesia, in particular with the development of thiopentone (Pentothal) and methohexitone (Methohexital/Brevital/Brietal).

The latter was an ultra-short-acting barbiturate anesthetic agent which was synthesized in 1956 and which lacked the twitching effects of some of the earlier methylated compounds. It rapidly became popular on both sides of the Atlantic Ocean and is still used in the USA. In the UK, a simple technique of giving small increments to a loading bolus was

popularized by Stanley Drummond-Jackson. He was undoubtedly skilled at the incremental methohexitone technique and was an avid proponent of ultra-light anesthesia. Unfortunately some of those who tried to emulate him were less successful and a number of high-profile anesthetic accidents in the 1960s resulted in the technique being condemned by the increasingly vocal anesthetic profession.

This professional opposition coincided with the development of diazepam – the first commercially available injectable (although it can be administered in a variety of ways) benzodiazepine in 1963. Despite its highly addictive properties, diazepam rapidly became a panacea for just about every condition known to man before it gradually found a more sensible level of usage. The intravenous formulation was not water soluble and so was dissolved in propylene glycol, an irritant substance which undoubtedly resulted in several cases of allergy or anaphylaxis as well as the risk of thrombophlebitis. Despite these disadvantages, by the late 1960s, intravenous diazepam was beginning to be offered as a serious alternative to general anesthesia for simple surgical cases. In the UK, this growth continued in a largely uncontrolled way throughout the 1970s and, in an effort to ensure some order within the dental profession, the UK government established a working party under the chairmanship of Dr WR Wylie in 1978. In his report, the concept of deep levels of sedation was essentially ended by a new two-part definition.⁴ Its relative simplicity has ensured that it is still in use today and it states:

Conscious sedation is the use of a drug or drugs to depress the central nervous system in order to produce a relaxed and cooperative patient with whom verbal contact can be maintained throughout a procedure.

The drug or drugs used must carry a margin of safety wide enough to render the unintended loss of consciousness unlikely.

The two key factors (verbal communication with the patient throughout the procedure and a wide safety margin of the sedative agent) immediately rendered using barbiturates useless. Indeed, at the time, the only possible single intravenous drug available that could satisfactorily fulfil the definition was diazepam. The report, and the constant prominent headlines in the press whenever a dental death occurred (however rare) added to a body of opinion that was being “politically” driven by the increasingly powerful anesthetic lobby. Papers such as that by Muir *et al.*⁵ demonstrated the huge safety margin of local anesthetics compared to general anesthetics. Indeed, the rarity of deaths related to local anesthesia makes it difficult to give a figure for the risk involved but it is probably between 1 in fifty million and 1 in a hundred million. How much sedation increases that risk

is equally difficult to assess but there is little doubt that conscious sedation as defined and practiced in the UK is very safe.

In the USA, sedation has travelled a different pathway. Nils Jorgensen is generally regarded as the father of intravenous sedation and he used a cocktail of drugs (pentobarbitone/scopolamine/pethidine/hyoscine) before also giving local anesthesia. Whilst these multiple drug techniques have remained popular in the USA, the UK has almost entirely developed single-drug techniques and these are described in more detail later.

Although Wylie's report was the first, it was immediately followed by two supplemental reports looking at the practical application of his recommendations. One of these was that the sedation could be given by the operator providing there was "an appropriately trained second person" present whose sole purpose was to monitor the patient. This role was frequently fulfilled by a (supplementary) dental nurse who could be given the additional training at minimal expense compared with the cost of employing a second clinician. However, in the early days of sedation the extent of any additional training for either the practitioner or the appropriately trained second person was ill defined and, in many cases, probably grossly inadequate. This resulted in the UK government requesting a further report and establishing a working party chaired by the late Professor David Poswillo.⁶ On publication, its fundamental premise was that virtually all outpatient (office) dental anesthesia should stop and that it should be replaced by simple, single-drug sedatives wherever possible. (In reality, the reverse happened for a short period before the General Dental Council, the regulatory body for the whole of dentistry in the UK, reinforced that "advice".)

This occurred in 1998 and 2 years later the chief medical and dental officers for England issued yet another report on sedation entitled "A Conscious Decision".⁷ This really did seal the fate of office-based anesthesia as can be seen from Table 6a.1. In its heyday, it is estimated that over 3 million anesthetics were being administered by dentists annually. Although the figures in Table 6a.1 only refer to the number of anesthetics being offered by the National Health Service (NHS), there is good empirical evidence to show that very few anesthetics are being administered in the dental office in the UK.

Table 6a.1 The decline in provision of NHS dental anesthesia.

In the year to 31 March	Cases of dental anesthesia
1998	350 000
1999	127 000
2000	45 000
2001	35 000
2002	11 000
2003 onwards	Very few cases

The reports on sedation in the UK, produced around the turn of the millennium, seemed to fuel the desires of every organization and society in existence to offer advice and recommendations. It is not appropriate to list them all in this chapter but they have had the effect of deterring many able practitioners from offering any form of sedation in general practice when there is a huge demand for such services and there is a clear evidence base for the safety of sedation techniques as defined by Wylie. The next section of this chapter, therefore, considers the techniques of sedation currently used in the UK along with some of the potential developments.

The role and scope of sedation

It is important to realize that the management of all patients occupies a spectrum of behavioral management. Behavior is not an easy word to define but is commonly thought of as a response or series of responses to a given stimulus. So-called "normal" behavior is even harder to define since it usually involves a somewhat vague comparison with a majority. Thus if most people who attend a dentist can sit in a waiting room and appear relaxed, the person who sits there crying in fear of his or her appointment is deemed to be behaving "abnormally". In reality, the borderline between so-called normal and abnormal can be very difficult to delineate. What is more important is the ability of the dentist to "manage" behavior in such a way that he or she can complete a patient's treatment with the minimum of stress – for either party! Behavioral management is not taught to any great extent in many dental schools, yet having some understanding of the subject can considerably ease the treatment experience of both the patient and the dentist.

Influences on behavior are usually divided into intrinsic (e.g. the will, emotional state, expectation, prior experience, etc.) and extrinsic factors (e.g. environment, culture, time of day, dentist's attitude, etc.). The dentist can easily and directly influence and adjust many of the extrinsic factors. Understanding and modulating the patient's response to the intrinsic factors is more complex but can be improved by training and experience. At the extreme end, behavioral therapy of various types is available, some of which are more effective than others. The most evidence-based of these is cognitive behavioral therapy (CBT) but other methods, including systematic desensitization, transactional analysis (TA), and rational emotive therapy (RET), can be effective. The main problem with all the above techniques is the time (and often cost) involved and this is not something everybody can commit to.

A simple progression from behavioral therapy is the use of therapeutic hypnosis. Hypnosis is controversial in some circles but can be very effective in inducing relaxation – indeed, the sensation is rather

like that of a Sunday afternoon snooze: one is remotely aware and yet able to feign total unconsciousness! As an “altered” state of consciousness, hypnosis is not well understood but it can demonstrate five different features:

- ability enhancement – allowing the completion of tasks not previously thought possible;
- memory variation – a facility to apparently improve memory retention or to eliminate known memories;
- pain control/relaxation – a diminished response to painful stimuli;
- age regression – the capacity to revert to an earlier part of one’s life;
- a hidden observer – the feeling that half of the mind is observing what the other half is doing or that life is “happening” and you are just watching it remotely.

The use of therapeutic hypnosis has been summarized by Chaves⁸ and he presents ten different possible indications for its use. These are somewhat different from the techniques used for counseling or smoking cessation, for instance, and readers who may wish to deepen their interest on the subject should read the full textbook mentioned above. Interestingly, it is only a short step from hypnosis to the next easiest type of sedation – relative analgesia or inhalational sedation as it is more commonly known in the UK.

Inhalational sedation is almost certainly the safest form of drug-induced sedation for reasons that are outlined below. It has been used in all sorts of environments from childbirth to wartime situations but its use in dentistry has been particularly beneficial in pediatric patients. Inhalational sedation is based on stage 1 of anesthesia which was first described by Guedel in 1937. In practice, nitrous oxide sedation had been used before Arthur Guedel described his classic stages of anesthesia and before any attempt was made to sub-classify sedation into various “planes”. The reality of a “continuum of sedation” is evident to all clinicians who have had adequate experience in administering nitrous oxide and is further discussed later in the chapter. For those in whom nitrous oxide sedation is inadequate there are the additional options of oral sedation or intravenous sedation prior to consideration of a full anesthetic. Oral sedation is probably the oldest form of sedation with patients self-administering alcoholic beverages or even naturally occurring narcotics in attempts to overcome their fears. The more judicious use of oral agents, formally prescribed in correct dosage, has centered on a variety of hypno-sedatives of which the benzodiazepines are currently the most popular. This can be traced back into the 19th century and remains a popular form of premedication and sedation to this day.

Similarly, the use of intravenous benzodiazepines has been the mainstay of sedation in the UK for the

last 30 years, based principally in the early years on diazepam and, more recently, midazolam. These are discussed further in the section on intravenous sedation.

Inhalational sedation

Much of this work is attributed to the late Harry Langa⁹ who popularized the term “relative analgesia”. This was based on Guedel’s description of the first stage of anesthesia – the analgesic stage. Langa (and various others) noted that there were degrees of analgesia which increased prior to stage 2 of anesthesia – the excitatory stage. Within the early stages were clinical signs that occurred including relaxation, paresthesia, euphoria, dreaming, and limited amnesia. Whilst not entirely predictable, many patients (especially children) benefited from these experiences and found dental treatment much easier to cope with.

However, whilst Langa would use the deeper ends of sedation (relative analgesia), in the UK the trend has always been to limit the maximum exposure to nitrous oxide to about 25–30% and not to err towards the higher levels required for relative analgesia. For this reason the term “inhalational sedation” is almost exclusively used and practiced in the UK. The machines used are largely the same as those in the USA with several safety features, including automatic shutdown in the case of oxygen failure, a dual pressure valve system which limits the maximum nitrous oxide to oxygen ratio, a ventilation bag and emergency override, and a pin-indexed fitting system for the gas cylinders.

As a result, inhalational sedation with nitrous oxide has had an excellent safety record with no serious cases of morbidity recorded. The slight potential for causing diffusion hypoxia (a condition that ensues as a consequence of the extremely low solubility of nitrous oxide in the blood thereby resulting in nitrous oxide “pooling” in the alveoli followed by it being re-breathed) is averted by the 30% minimum oxygen levels and monitoring the patient carefully following termination of sedation.

The disadvantage of nitrous oxide could be considered to be its lack of potency. It is undoubtedly a weak agent and this has almost certainly enhanced its profile as the prime choice for inhalational sedation. Another disadvantage, however, is that there is growing evidence that chronic exposure to even small levels of nitrous oxide may result in toxic effects to the individual thereby putting both the clinician and his or her assistants at risk. To minimize this risk, the use of scavenging equipment should be employed to reduce the atmospheric concentration to as low a level as possible. Current UK recommendations are for an 8-hour, time-averaged level of no more than 100 parts per million of nitrous oxide in room air and this may be reduced to 50 ppm in the not-too-distant future. It is necessary to use closed breathing circuits

and active scavenging to get the background level down to this figure if inhalational sedation is being used on a regular or continuous basis.

The possibility of using other agents for inhalational sedation has also been tried. The early results with sevoflurane (a modern halogenated ether) have been excellent and, like nitrous oxide, it has extremely low blood solubility. The consequential rapid rise in gas partial pressure within the blood makes it very fast acting and also gives a very rapid recovery. However, unlike nitrous oxide, the potency of the agent itself is considerable and full anesthesia can too easily be induced. For this reason it is unlikely ever to find its way into mainstream usage within the UK.

Oral sedation

The history of prescribed oral sedation can probably be traced back to chloral hydrate although the use of some of the naturally occurring narcotics probably predates it. Morphine, for example, was first isolated from opium in 1803 by the German pharmacist FWA Sertürner, who named it after Morpheus, the god of dreams.

Chloral hydrate itself was introduced into therapeutics more than 125 years ago and became popular as a sleeping potion. It was the first ever synthetic CNS depressant and appears to work through its reduced metabolite, trichloroethanol – itself an anesthetic agent. In the middle of the last century other drugs, particularly of the phenothiazine group, were developed and found to be useful as mild hypnotic sedatives. The development of the benzodiazepines, especially in the 1960s and 1970s, transformed oral sedation with drugs that were more powerful as anxiolytics and yet which carried a wide safety margin; so wide that there were many reports of unsuccessful suicide attempts of people who had overdosed on benzodiazepines (BZDs) alone. Indeed the use of oral BZDs has been supplemented with transmucosal preparations including nasal drops, sublingual gels and rectal pessaries.

In practice, the use of a simple, relatively short-acting BZD such as temazepam given 1 hour preoperatively will relieve the apprehension of a significant majority of patients. The simplicity of administration, coupled with its dependable effectiveness and low cost, make it an ideal agent for those whose anxiety is moderate but who nonetheless suffer considerable stress when facing treatment. Patients who are medicated in this way tolerate the use of local anesthetics much more easily than non-sedated patients and exhibit lower levels of body stress responses (heart rate, blood pressure, ventilation rate, etc.). On the negative side, they will be unable to drive or operate machinery for the remainder of the day of administration and they will need to be accompanied home by a competent adult. There is also some evidence

that even a single dose of a BZD will affect routine sleep patterns for up to a week and some patients find this disturbing. The desire to develop a drug which does not have these negative effects, i.e. one which provides true anxiolysis without sedation, therefore continues.

Most recently interest has been focused on negative allosteric modulators (NAMs) of the metabotropic glutamate receptor 5 (mGluR5). An early example of this is fenobam (a product which has a similar mode of action to the NAMs) which demonstrated efficacy in patients with generalized anxiety disorders after repeated administration. The translation of this into a drug suitable for reducing anxiety in an acute dental setting has yet to be established and early results have only been partly successful. However, the ideal of a product which provides true anxiolysis (without the need for hypno-sedation) remains a goal for future development.

Intravenous sedation

The benzodiazepines (BZDs) are versatile drugs which have been used orally, intramuscularly, intravenously, rectally, and transmucosally. Pharmacologically, each one has at its base a fused dual ring of benzene and 1–4 diazepine. Whilst the benzene ring is basically a hexagon, the diazepine ring is a heptagon with positions 1 and 4 of the 7 corners being nitrogen rather than carbon atoms. (For those who enjoy the science, see Cooper, Bloom and Roth's book.¹⁰) For those who may be baffled by the science, what is important to understand is that by substituting or adding various radicals to the basic BZD ring, the pharmacokinetics and dynamics of the compounds change considerably. A range of activity varying from agonist through antagonist to inverse agonist has been described and these properties can be adapted to differing clinical requirements. In addition, the solubility of the compounds varies and, for intravenous usage, there are clear advantages to having a water-soluble drug. For orally consumed compounds, absorption is a more important factor and this is another marked variable. All the BZDs, however (whether agonist or inverse agonist), are thought to bind to a specific receptor, analogous to or part of the GABA_A receptor (see Fig. 6a.2) at the nerve synapses.

These receptors essentially control the flow of chlorine ions in and out of the nerve axons – inward flow (agonists) producing relaxation and anxiolysis and outward flow (inverse agonists) producing agitation and anxiety. Antagonists have the effect of displacing both agonists and inverse agonists thereby "neutralizing" the effect on the GABA receptor. Pharmaceutical companies have created thousands of benzodiazepines over the years since it is difficult to predict their exact properties along the activity spectrum without *in vivo* testing. Despite this, only three

Fig. 6a.2 Functioning of the GABA_A receptor.

benzodiazepines are currently used in the UK for intravenous sedation:

- diazepam (now usually administered in an emulsified form to avoid the complications of thrombophlebitis);
- midazolam (a water-soluble, shorter-acting alternative);
- flumazenil (an antagonist, usually reserved for emergency use).

The similarity of the compounds is illustrated in Fig. 6a.3.

Intravenous BZDs are usually administered via an indwelling cannula inserted into either the dorsum of the hand or the antecubital fossa. They should be administered slowly in small increments, carefully observing the responses of the patient. With diazepam, the dose given was usually high enough to induce Verrill's sign. This consisted of a degree of partial ptosis that would bisect the pupil of the eye.

Fig. 6a.3 Midazolam, diazepam, and flumazenil.

However, it is now generally agreed that this level of sedation is too profound and the aim is to produce a more relaxed but less sedated patient. To this end, Eve's sign is used as a useful indicator of the early signs of loss of motor coordination. The sign is simply tested by asking the patient to touch his/her nose with one finger. As early relaxation occurs, the finger usually falls short – touching the top lip only. Many patients giggle when this occurs thereby adding a further indicator that they are becoming more relaxed.

In the general outpatient (office) setting, patients of ASA 1 and 2 are treated, while patients of ASA 3 or above are usually referred to a specialist unit. Preoperative assessments consisting of a full medical history, an assessment of ASA status, blood pressure, and body mass index (BMI) are usually undertaken. BMI is a ratio that calculates the degree of obesity of a patient and is the weight of the patient in kilograms divided by the height in metres squared. The ideal range is between 20–25, and patients who have a BMI of 35 or over begin to progressively demonstrate an increased risk of airway obstruction. While this can be monitored by the use of pulse oximetry, it is wise to use caution in treating patients who are significantly obese. The respiratory depression that is a side-effect of the BZDs together with the tendency of obese patients to obstruct their airways (or more seriously to suffer from sleep apnea) can prove a fatal combination and deaths from this have been reported by endoscopists. The advent of flumazenil has, to some extent, alleviated the concerns regarding BZD overdosage but it is unsafe to rely on an antidote to compensate for unsafe medical practice. Some practitioners use flumazenil as a reversal agent, in the same way that the paralyzing agents used during modern general anesthetics can be reversed using neostigmine. Others argue that the cost of the agent and the risk of resedation, however small, proscribe such use.

Despite the widespread use of the BZDs they do not fulfill all the requirements of an ideal sedative which should principally be aimed at reducing anxiety rather than causing hypno-sedation. At its simplest, the ideal drug would have no hypno-sedative effects but would simply remove the fear and anxiety commonly associated with dental treatment. Such a

drug would be best administered orally since many dental phobics often fear any form of injection including venipuncture. Although this can be ameliorated by using topical local anesthetic creams such as amethocaine or EMLA (a eutectic mixture of procaine and lidocaine), it still remains problematic for many patients. This has not stopped efforts to improve on the BZDs and, in the mid-1980s, a new class of drug was licenced.

Propofol is a 2,6-di-isopropylphenol with marked sedative-hypnotic and anesthetic properties. It is minimally soluble in water and so is formulated as an emulsion for clinical use. Propofol is highly lipophilic and distributes widely in the body. It has a three-phase model half-life of approximately 2–4 minutes in the alpha phase, 30–45 minutes in the beta phase and around 4–60 hours in the gamma phase. Propofol is rapidly and effectively metabolized by the liver prior to being eliminated through the renal system. Following administration, the clinical effect of sedation or hypnosis (depending on dose administered) occurs within a minute and usually lasts for 5–6 minutes.

Over the last 10 years, propofol has become the agent of choice for induction of general anesthesia although maintenance is more common with the modern volatile agents (see later). It has an excellent safety profile and, although it causes some decrease in both systolic and diastolic blood pressure (possibly by up to 25%), there is minimal change in heart rate. Cases of respiratory depression and apnea are also common. The cardiovascular and respiratory effects of propofol do not give cause for serious concern in otherwise healthy patients.

The use of propofol as a sedative in the UK has been restricted due to the risk of achieving unintentional anesthesia. However, the advent of patient-controlled sedation (PCS) (see Figs 6a.4 and 6a.5) has

Fig. 6a.4 The use of patient controlled sedation.

Fig. 6a.5 Microprocessor controlled pump.

allowed it to gain some popularity. PCS is an adaptation of patient-controlled analgesia (PCA). Drugs (whether analgesics or sedatives) are administered using a microprocessor-controlled pump which has two essential features. The first of these is the ability to adjust the dose administered; the second is the capacity to create a 'lock-out' period during which time the machine will not administer any agent even when prompted by the patient. Research into both the use of PCA and PCS systems has demonstrated that patients consistently administer less of the agents than would be the case if they were administered by a clinician.

General anesthesia

Despite significant advances in sedative techniques, there remains a number of patients who still require full anesthesia either as a result of their own anxiety or due to the complexity of the procedures. The consequence of effectively banning office anesthesia in the UK has been a marked increase in both the number of referrals to hospital units and the number of cases being seen as emergency admissions. All such patients who are accepted for anesthesia are treated by trained anesthesiologists – there being no concept of anesthetic nurses in the UK.

The last 20 years have seen a significant change in practice in the UK, with the laryngeal mask airway (LMA) becoming almost standard as a means of protecting the airway (Fig. 6a.6). Since its invention by Dr Archie Brain¹¹ in 1983 its use has grown exponentially both in the UK and around the world. It has been modified in various ways such that different types are now available. The inflatable diaphragm expands in the oropharynx, allowing the exchange of gases while at the same time protecting the larynx from any falling debris. After being placed by the anesthetist, the flexible LMA especially is easily

Fig. 6a.6 A rigid (lower) and flexible (upper) laryngeal mask side by side. The cuff is inflated and sits neatly in the oro-pharynx.

manipulated by the surgeon so that it does not interfere with the operation site.

In terms of induction and maintenance of anaesthesia, the use of propofol and sevoflurane is most common using oxygen and nitrous oxide as carrier gases within the breathing circuit (or system as it is more correctly known). The technical aspects of anaesthesia have, however, improved significantly, with electronic equipment capable of monitoring almost every aspect of everyday practice. While some argue that this has reduced the profession to little more than technocrats, there can be little doubt that improved monitoring equipment has contributed to an increased safety profile. On the negative side, it has added to the induction time required by the anaesthetist, as all the equipment has to be attached in some form to the patient. In a social health care system this could be considered to be less problematic than in an independently funded one but it still has to be considered in terms of cost and benefit. Since the potential benefit is so great, there can be little doubt that such monitoring can be justified in routine use.

Conclusion

Dentistry, surgery, and anaesthesia have been intricately linked from the earliest times of discovery. Most recently, sedation has had an increasingly prominent role within the dental profession and its increasing use should ensure that this continues to be the case for many years to come. However, this will be dependent on a demonstrable safety profile and an excellent therapeutic effect. In the UK, the controlled use of conscious sedation should ensure that this remains the case.

Chapter 6b

Sedation and General Anesthesia in Oral and Maxillofacial Surgery: A US Perspective

Richard C. Robert

In the USA, office-based anesthesia for oral and maxillofacial surgery is considerably different from that which is practiced in the UK. In the US oral and maxillofacial surgeons train side-by-side with anesthesiology residents in teaching centers, as well as within their own departments during their 4–6 years of training. Once in private practice, largely using the operator–anesthetist model, they offer the full range of anesthesia services as defined by the American Society of Anesthesiologists. These include minimal sedation, moderate sedation, deep sedation, and general anesthesia. The anesthetic agents, monitoring and emergency preparedness for this office-based anesthesia are quite similar to those employed in free-standing and office-based outpatient surgery centers. The most frequently used anesthetic agents are propofol, midazolam, fentanyl, ketamine, and, in some cases, sevoflurane. Commonly a balanced approach with multiple agents is employed. Typical monitoring includes continuous electrocardiogram (EKG), blood pressure and pulse, pulse oximetry, auscultation with a pretracheal stethoscope, and, with increasing frequency, capnography. A requisite for membership in the American Association of Oral and Maxillofacial Surgeons is periodic office-anesthesia evaluations to assure patient safety. This process is reviewed by the American Society of Anesthesiologists to ensure consistency with ASA guidelines.

Conclusion, 114

Office anesthesia for oral and maxillofacial surgery in the US today is vastly different from that seen in the UK. A wide range of surgical procedures is performed in an office setting under sedation and light general anesthesia. The difference is largely due to the effectiveness of professional organizations in the US that have been formed by oral and maxillofacial surgeons, as well as those with which they have chosen to become affiliated.

Historical perspective

The 19th century after Wells and Morton

The year is 1883 and Sophie is scheduled to have her painful tooth extracted at the office of the Colton Dental Association, with Professor Colton himself (Fig. 6b.1) providing nitrous oxide anesthesia. Although Sophie would have normally dreaded such an appointment, she is now almost enthusiastic. At this point in his life Gardner Colton¹ is arguably the most famous anesthetist in the world. During the 20 years over which he has been delivering dental anesthesia, he has traveled to the Universal Exhibition and First International Congress of Medicine in Paris and impressed audiences in both Paris and London with nitrous oxide anesthesia. In the US he now has offices in St. Louis, Chicago, Brooklyn, Cincinnati, Boston, Baltimore, and Philadelphia and over 100 000 patients have been successfully treated.^{2,3}

From reports she has received from acquaintances who have also had extractions at the Colton Dental Association, Sophie feels that the anesthesia she will receive will be far more desirable than any of the other types of anesthesia about which she has heard. Ether, which has been used for major surgical procedures, sounds terrible. It takes a long time for the patient to fall asleep, and the smell is disgusting. Then, once the operation has been completed and the patient awakes, it is to bouts of uncontrollable retching and vomiting. Worse yet, she has heard of mysterious unexplained deaths associated with chloroform, the other popular anesthetic of the day. So drifting off

Fig. 6b.1 Gardner Quincy Colton 1814–1898. Reintroduced nitrous oxide for exodontia during the 1860s and popularized its use in the US and Europe. (Illustration courtesy of Yale Medical Historical Library.)

in a euphoric state under the influence of Professor Colton's nitrous oxide is in Sophie's opinion the best of all anesthetic alternatives.

As she drifts off into somnolence, Sophie is not aware of the true nature of the "anesthetic" to which she is about to subject her body. Colton will watch her breathe the gas until she exhibits color changes.³ She will pass through pallor to the shades of blue of cyanosis, and then the gas will be removed. At that point there will be about 2 minutes of working time before she once again "pinks up", and it is during these 2 minutes that her surgery will be performed. If she begins to awake before the procedure has been completed, she will again be given the nitrous oxide until she becomes cyanotic once more. This time when she "pinks up", she will be allowed to awake with her tooth extracted. She will be pleasantly surprised that she has been "asleep" through the entire procedure and felt no pain during her surgery. Sophie does not know that the "anesthetic" which causes her to lose consciousness is actually asphyxia from the hypoxic state into which she will be rendered by exclusion of oxygen from the gas that she breathes. She also does not appreciate the fact that Colton himself does not thoroughly understand his own technique and falsely believes that the oxygen to which the nitrogen molecules are bonded in nitrous oxide will maintain his patients' oxygenation during the surgical procedure.

Of course Sophie is not a real patient, rather she is a composite of some 200 000 patients who underwent nitrous oxide "anesthesia" performed by Gardner Colton from the 1860s to 1890s. In large part, due to Colton's efforts in its promotion, nitrous oxide was to remain the favorite anesthetic for exodontists and oral surgeons for three quarters of a century, both in the US and abroad. But how was it that nitrous oxide should assume such a position in the world of anesthesia after Wells' unsuccessful demonstration at Massachusetts General Hospital which had been described as pure "humbug"? The tale is an interesting one, worthy of repeating.

During the several years following Wells' failed attempt to demonstrate nitrous oxide anesthesia, Colton (who had administered the initial nitrous oxide anesthetic to Wells) became involved in other scientific pursuits, including the development of the telegraph and the electric engine. He moved to California during the Gold Rush, but was unsuccessful in his attempts at prospecting. On returning to San Francisco he was appointed as the first Justice of the Peace. In this capacity he was in charge of the sale of town lots in the city, which proved to be controversial. Colton ultimately left California a rich man, but with a tarnished reputation. He returned to Boston where he had begun his adult career.

During Colton's hiatus from the world of dental anesthesia, word of Morton's successful demonstration of ether at the "Ether Dome" spread to physicians and dentists throughout the world. This interest in

turn led to further experimentation. Notably, James Simpson,^{4,5} an Edinburgh obstetrician, became obsessed with the idea of finding another inhalation agent which lacked the disgusting smell of ether and its flammable properties. He and some fellow inquisitive scientists set out to test other agents on themselves. On Thursday evenings they met at Simpson's home and inhaled various chemicals to personally assess their anesthetic attributes. On 3 November 1847, one of the "chemicals de jour" was chloroform, which had been originally produced 16 years earlier, but for which no one had come up with a practical use. On sniffing chloroform, Simpson and his friends were transported to another world and finally into the "arms of Morpheus". Simpson found that chloroform had such desirable properties as a more rapid onset than ether, a less unpleasant smell, non-flammability, and low cost. The new agent was affectionately dubbed "Chlory", and it was to dominate the anesthetic world over the next several decades.

Chloroform became the favored anesthetic of American Civil War surgeons because of its more rapid onset of action accompanied by a decreased incidence of postoperative vomiting and nausea.⁶⁻⁹ There were periodic reports of deaths during anesthesia, presumably from cardiac dysrhythmias and postoperatively from liver failure. Nonetheless, to combat surgeons these were risks which they were willing to undergo for the rapidity of chloroform's induction. After the Civil War, ether regained prominence in the US, but chloroform continued to be the agent of choice in the UK for a number of years.

Neither ether nor chloroform were widely accepted by dentists for exodontia. The dental world awaited an agent which had a pleasant smell, relatively rapid onset and which had an "aura of safety" about it. And who could have been more qualified to bring this agent forth than the very man who had first demonstrated the use of inhalation anesthesia on Horace Wells, Gardner Colton himself.

After his return to the East Coast, Colton¹ fell on hard times when he lost the money he had made in California in an investment in the ill-fated Salt Works of Syracuse. This prompted his resuming his lectures and demonstrations of nitrous oxide. He ultimately associated himself with two eminent dentists in New York City which resulted in the formation of the Colton Dental Association. In 1898, a year before he died, Colton published a book summarizing his anesthetic accomplishments. He recorded that nitrous oxide had been administered to 193800 patients whose ages ranged from 3–90 years, reportedly without a fatality.

It is difficult to say why Colton held so firmly to his belief that he was providing adequate oxygenation for his patients with his 100% nitrous oxide approach. We do know that he never completed his medical studies which he had undertaken in 1842, 2 years before he administered nitrous oxide to Wells. He had entered the Crosby Street College of Physicians

and Surgeons in New York, but decided that he did not wish to pursue a medical career, stating that he had elected to "throw physic to the dogs".¹ Thus "Professor Colton" was not really a professor at all, but merely a popular lecturer with minimal medical background who lectured on chemistry with an emphasis on nitrous oxide. Unquestionably, however, he was endowed with certain perceptive qualities which enabled him to become past master at rendering patients unconscious with nitrous oxide hypoxia without killing them.

Other physicians and scientists studying nitrous oxide suspected that Colton's method did, in fact, induce a hypoxic state. Opposing views developed, and in 1868 Edward Andrews, a Chicago surgeon, advocated that oxygen be utilized with nitrous oxide to provide a safer anesthetic.¹⁰ However, with the equipment available at the time, a satisfactory combined delivery was not practical. Ultimately Thomas Evans, an American dentist living in Paris who had observed Colton's demonstrations there in 1867, introduced the concept of compressing the gas into a liquid form which could be more practically stored in containers.³ By 1881, the SS White Company had developed a storage cylinder for nitrous oxide which led to increased popularity of the agent for exodontia.¹¹

As attempts were being made to provide a safer inhalation anesthetic, other developments were taking place in New York which would ultimately impact dentistry and oral surgery just as profoundly as the discovery of surgical anesthesia. William Stewart Halsted,^{12,13} considered by many to be the "Father of American Surgery", began his landmark work in the development of effective local anesthesia. Halsted and a colleague, Richard J. Hall, administered nerve blocks with cocaine and actually even demonstrated systematically the application of local anesthetic for dentistry and oral surgery. Unfortunately, like so many of the early pioneers, Halsted and Hall administered the agent they were investigating to themselves and developed addiction to the drug which they were studying. Hall ultimately had to leave academia altogether and moved to California, where he remained addicted to cocaine until the end of his life. Halsted, in an attempt to overcome his addiction, entered the Butler Hospital in Providence Rhode Island for treatment. The "treatment" basically involved the transferral of his addiction from cocaine to morphine, to which he remained addicted until his death in 1922. Nonetheless, in his addicted state, he continued to make outstanding contributions to the development of surgery in the US and was ultimately appointed Surgeon in Chief and Professor of Surgery at Johns Hopkins in 1892.

As the 19th century came to a close, yet one more important event would take place that would ultimately enable anesthesia for oral and maxillofacial surgery to enjoy the success it holds today. German medical science, never to be overshadowed in the

19th century, produced the first of a line of drugs which would provide the cornerstone for outpatient anesthesia. In 1903, Emil Fischer, doyen of German organic chemists and Nobel laureate, joined pharmacology professor Joseph von Mering in the development of a hypnotic drug, diethyl barbituric acid, which was synthesized from malonic acid and urea. It was introduced on the market under the name Veronal® by their parent company Bayer as the first commercially available barbiturate.^{14–17} However, it would be several decades before a truly short-acting barbiturate would be developed that would enable patients to undergo anesthesia for their surgical procedures and yet go home at the end of the day.

The 20th century

Early decades

As the 19th century passed into the 20th, the “Great Transatlantic Debate” was finally coming to an end. For half a century the controversy had raged as to which was the better and safer anesthetic. Was it Morton’s “Yankee Dodge” as British surgeon Liston had coined ether,^{18,19} or was it Simpson’s chloroform which had dominated in the UK? In the 1880s, due to the frequent reports of deaths associated with chloroform anesthesia, a panel of experts was assembled to assess the agent’s safety. The panel was termed the “Hyderabad Commission” after the Nizam of Hyderabad, the wealthy Indian potentate who funded the study.⁸ It was chaired by a British medical officer, Dr Edward Lawrie, who had trained in Edinburgh, which had been “Chlory’s” birthplace. As one might anticipate, the commission’s output was somewhat tainted by Lawrie’s involvement.²⁰ Its report was rather inconclusive, which was held by Lawrie to substantiate the safety of chloroform. The prestigious British medical journal *The Lancet* published the conclusions of the Hyderabad Commission, but failed to accept the commission’s interpretation of the data. Instead, they encouraged Britain’s eminent physiologists to further study the problem, and the results of their studies left no doubt. Indeed, the fears regarding chloroform were justified – chloroform was not a safe anesthetic after all. Their conclusions were adopted in 1892 and confirmed again in 1901 by the British Medical Association’s Committee of Anaesthesia and published for all the world to see.⁸

Although ether had won the debate, its doing so was actually a mixed blessing. The difference in the attributes of ether and chloroform had actually been responsible for a dichotomy in the culture of anesthesia in the US and the UK. As we have seen, chloroform depressed respiration, was a myocardial depressant which induced ventricular dysrhythmias, and was responsible for hepatorenal toxicity.²¹ Consequently, it was necessary for those who administered chloroform to be physicians, not just technicians or nurses. Thus, in the UK, where chloroform was dominant,

the profession of anesthesiology developed early on. However, in the US, where ether reigned supreme, it appeared that there was no need for physicians to take on such a mundane task as periodically placing a drop or two of ether on the mask as the surgical patient slept. As opposed to chloroform, ether was incredibly safe. It neither caused respiratory depression nor induced arrhythmias. It was not histotoxic, and it was virtually impossible for even the inexperienced to give a life-threatening overdose of the anesthetic.¹⁸

So safe was ether that its administration could be relegated to technicians and nurses. These lesser-trained anesthetists often became more skillful than the surgeons for whom they worked, who only gave anesthetics infrequently themselves. The nurses were cheap, did not argue with the surgeon, and yet did an admirable job in providing anesthesia with ether. With nurses performing the task, there appeared to be no need for physicians to become involved with the process at all, and when they did so, they were poorly paid.²² Anesthesia was the “poor stepchild” of surgery and had no academic foundation in medicine and no journals. Eventually Francis H. McMechan, one of the few physicians to carry the torch for anesthesiology as a specialty of medicine, persuaded *The American Journal of Surgery* to provide some coverage for anesthesia which resulted in the *Quarterly Supplement of Anesthesia and Analgesia* in 1914. Not until 1922 did a periodical devoted solely to anesthesia appear, *Current Researches in Anesthesia and Analgesia*.²²

Although the very success of ether had thwarted the development of anesthesiology in the US, at the turn of the century pioneering physicians in the midwest were to finally plant the seeds for the establishment of anesthesiology as a profession. Principle among them were Ralph Waters at the University of Wisconsin and John Lundy at the Mayo Clinic.²³ In the same pioneering tradition which had resulted in the western expansion of the US, these physicians set out on a path of their own which enabled anesthesiology to become a profession in its own right, and assured that it was well founded in science and medicine. We will see more of John Lundy as we explore the evolution of “balanced anesthesia” on which anesthesia in oral and maxillofacial surgery is based to this day.

Although departments of anesthesiology were finally becoming established during the early decades of the 20th century, ether and nitrous oxide continued to be the only practical anesthetic agents available. Pharmacologic research got underway to identify better barbiturates and local anesthetic agents. Various other inhalation agents were explored, but none demonstrated clear-cut advantages. At least improved anesthesia machines were forthcoming, usually from the dental sector. In 1902 Charles Teter a dentist from Cleveland, designed and modified an improved nitrous oxide and oxygen anesthesia

machine. Six years later in 1908 another dentist, Jay Heidbrink, introduced flow meters to accurately control the delivery concentration of gases.¹⁰

Although Halsted and others had demonstrated the possibility of effective local anesthesia, cocaine did not prove to be an agent which would be applicable to the treatment of the masses of dental and medical patients. Once again, German medical chemistry came forth with a solution. In 1904, chemist Alfred Einhorn patented 18 para-aminobenzoic derivatives, one of which was given the name "Novocaine".^{24,25} Although Novocaine became the standard local anesthetic of the time, it had inherent drawbacks: many patients were highly allergic to para-benzoic acid from which it was derived and relatively high doses of epinephrine were required to maintain the anesthetic in the area of injection. The search for better agents continued until the advent of lidocaine, the first amide anesthetic, in 1949.¹³

The mid-20th century

Up until the early decades of the 20th century, efforts had been directed at finding the ideal mono-anesthetic agent which would promptly "put patients to sleep" and allow their rapid arousal at the end of the surgical procedure. However, one farsighted pioneer surmised that it was unlikely that a single chemical could provide all of the desired effects requisite to surgical anesthesia. In 1894, John Silas Lundy^{23,26} (Fig. 6b.2) was born in the Dakota territories. He originally practiced anesthesia in Seattle, but was ultimately recruited by Will Mayo to join him at the Mayo Clinic. At Mayo Lundy developed the concept of "balanced anesthesia" which relied on the combination of a number of different agents including premedication, regional anesthesia and light general anesthesia. Lundy's approach was based on the concept that the smaller doses of multiple agents in a balanced anesthetic would be associated with fewer complications and would provide a more desirable anesthetic experience for patients. He worked with pharmaceutical firms in clinical trials on various intravenous agents, and was one of the first to investigate the clinical use of thiopental (Pentothal Sodium) in 1934. In Lundy's technique small intermittent boluses were administered to maintain the patient at the desired level of anesthesia. Although his patients tended to awaken more rapidly with fewer after effects than with inhalation anesthesia, Lundy strongly felt that an overnight stay in the hospital was still necessary.¹¹

Just 3 years after Lundy's introduction of Pentothal Sodium to the anesthetic world, Adrian Hubbell^{3,11,27} (Fig. 6b.3), a newly graduated dental student from California, undertook his oral surgery training at the Mayo Clinic. Once he was introduced to intravenous anesthesia during his training, he became fascinated with the idea of adapting the technique to office oral surgery practice. Like so many other pioneers before

Fig. 6b.2 John Silas Lundy developed the concept of balanced anesthesia in the 1920s and published the first account of the clinical use of Pentothal Sodium. (Reproduced from Rabbitts JA, Bacon DR, Nuttall GA, Moore SB. Mayo Clinic and the origins of blood banking. *Mayo Clin Proc* 2007; 82(9): 1117–18 by permission. Copyright © 2007 Quadrant HealthCom.)

Fig. 6b.3 Adrian Hubbell. Completed his residency training at the Mayo Clinic in 1940 and developed the concept of office-based anesthesia in his oral surgery practice in Long Beach, California. (Photo courtesy of The American Association of Oral and Maxillofacial Surgeons.)

him, Hubbell decided to try the anesthetic himself and had his third molars removed under Pentothal anesthesia. On completing his training Hubbell returned to California and joined an established oral surgeon Berto Olsen in private practice. Olsen's practice had traditionally been a nitrous oxide practice, but he consented to change over to Pentothal Sodium under Hubbell's guidance. Over the next several years, Hubbell perfected his office anesthetic technique with Pentothal Sodium, and in 1945 he opened a 6000 sq. ft. oral surgery clinic in Long Beach, California. Over the next several decades more than 300000 anesthetics were to be administered in Hubbell's office without a single fatality.

Word of Hubbell's success in California was soon to spread throughout the country. He had frequent visitors to observe his office operation, and some of these entreated him to put on courses on intravenous Pentothal anesthesia. Consequently, in the mid-1950s

Fig. 6b.4 Harold Krough. Worked with Adrian Hubbell to establish courses in the use of Pentothal Sodium for office-based surgery during the 1950s. (Photo courtesy of The American Association of Oral and Maxillofacial Surgeons.)

from 1953–1958, Hubbell and an east coast colleague, Harold Krough (Fig. 6b.4), from Washington, DC fielded courses on the technique.

At the Mayo, Hubbell had learned Lundy's techniques but questioned one of his primary tenets, i.e. that balanced Pentothal anesthesia could only be performed with an overnight hospital stay. Hubbell amply demonstrated that this type of anesthesia could indeed be performed on an outpatient basis with safety and efficiency. His successful demonstration of office-based Pentothal anesthesia provided the foundation for the adoption of outpatient surgery as the primary form of surgical care delivery in virtually all surgical specialties by the end of the 20th century.

Another important mid-20th century pioneer in intravenous anesthesia was Niles B Jorgensen of Loma Linda University.^{2,3,27} Jorgensen also advocated a balanced approach, but preferred a lighter level of sedation. The "Jorgenson technique" entailed the administration of three agents: pentobarbital, meperidine, and scopolamine.^{28–30} His technique enjoyed an excellent safety record and laid the groundwork for the use of "conscious sedation" in all fields of dentistry.

By the end of the century's fifth decade, another ultra-short-acting barbiturate became available. Eli Lilly introduced sodium methohexital (Brevital®) which was initially field tested in Hubbell's private practice over a 2-year period.³¹ In 1960 it was released to the profession and rapidly replaced Pentothal Sodium as the anesthetic agent of choice in most oral surgery practices. It was to remain so until the end of the century.

Latter portion of the 20th century – the 1960s, 1970s, and 1980s

Barbiturate-based "balanced" anesthetic approaches with nitrous oxide gained wide acceptance in the profession, but the technique was not without its

shortcomings. Preoperative anxiety often translated into relatively larger doses of barbiturate. This tended to make laryngospasms more likely and prolong recovery as well. In addition, barbiturates lacked analgesic properties, and in some cases caused hyperalgesia. Consequently, during injections of local anesthesia, or when there was inadequate local anesthesia, the patient would often respond violently. Fortunately, advancements in pharmacologic chemistry made it possible to largely overcome these problems. Soon additional intravenous agents were added to the "balanced" combination of drugs.

An important new family of anesthetic drugs, the benzodiazepines, appeared in the late 1950s and early 1960s.³² Since that time the benzodiazepines have become an essential part of balanced anesthesia in outpatient surgery centers and oral and maxillofacial surgery offices as well. The first of these agents which enjoyed wide acceptance in dentistry³³ and oral and maxillofacial surgery was diazepam, introduced in 1963. Its anxiolytic and sedative properties were augmented by a profound amnestic quality as well. When it was administered in combination with the opioid meperidine prior to the short-acting barbiturate, a smoother anesthetic course could be achieved.

Another new family of anesthetic drugs which emerged during the 1970s was phencyclidine derivatives.³⁴ Phencyclidine itself was synthesized in the late 1950s, but was found to cause significant hallucinations and delirium. Experimental work continued with the investigation of a number of other derivatives. Finally, ketamine was synthesized in the mid-1960s and released in 1970. Unlike most other anesthetic drugs (with the exception of narcotics) ketamine had analgesic properties and tended to raise blood pressure as opposed to lowering it. Its CNS effects were largely centered in the thalamic relay centers which led to a state of anesthetic "dissociation". Although ketamine, like phencyclidine, also had the potential for causing dysphoria, it was found that the latter could be largely overcome by administration of benzodiazepines prior to ketamine.

Over the several decades at the close of the 20th century, health care costs would lead hospital administrators and insurance carriers to explore the idea of outpatient surgery, not unlike that which had been employed in oral and maxillofacial surgery offices throughout the country for decades. Indeed, between the 1980s and the first decade of the 21st century, there was a shift of approximately 75% of surgery procedures from the inpatient hospital setting to a variety of ambulatory venues. These included hospital outpatient surgery centers, free-standing outpatient surgery centers, and surgeons' offices.³⁵

An important element in safe delivery of outpatient surgery is rapid and complete recovery before the patient is discharged. Consequently, there was a need for shorter-acting drugs to ensure that the patients could be discharged without being overly

obtunded. Fortunately, pharmacologic research led to such agents. The first of these was fentanyl,³⁶ an anilidopiperidine related to meperidine, which was introduced in the 1970s. It was 100 more times more potent than morphine, had a shorter duration of action, and was less likely to cause nausea. Within the next decade midazolam, a shorter-acting benzodiazepine,³⁴ also became available. This new agent midazolam not only had a shorter duration of action than diazepam, but was soluble in blood and provided more profound amnesia.

During the latter decades of the 20th century, technologic advancements paralleled those in pharmaceutical research. Electronic monitoring devices gained popularity in all types of outpatient anesthesia, whether in freestanding surgery centers or in oral and maxillofacial surgery offices. Monitors included electrocardiogram (EKG), blood pressure, and pulse oximetry, which were usually accompanied by a pretracheal stethoscope.³⁷ Monitoring standards were introduced and were soon mandated for accreditation of facilities.

Although the barbiturate induction agents Pentothal Sodium and methohexital had been “workhorse” anesthetic agents for half a century, a new agent, propofol^{38,34} was to be introduced in the 1980s and 1990s which would ultimately replace the barbiturates. This new agent propofol was rapidly redistributed and metabolized like barbiturates, but had other desirable characteristics as well. It did not tend to predispose to laryngospasms, it had innate antiemetic properties and patients awoke with a feeling of well-being.

The 21st century

By the turn of the century propofol had largely replaced Pentothal Sodium for anesthetic induction in hospitals and outpatient surgery centers. However, the move to propofol took place much more slowly in oral and maxillofacial surgery offices. The incremental Brevital[®] technique which Hubbell had popularized in the 1960s was well entrenched and few saw the need to replace the technique with the expensive new agent propofol. However, within the first few years of the 21st century this was all to change. Due to a problem with contamination at the production plant, there was a hiatus in Brevital[®] (methohexital) availability.³⁹ This resulted in many oral surgeons having to convert to propofol as their primary intravenous anesthetic agent. When methohexital once again became available on the market, many practitioners elected to not return to methohexital because they had come to appreciate the more desirable anesthetic properties of propofol.

The first decade of the 21st century has also seen a broadened view of “balanced” anesthetic techniques. Many anesthesiologists and oral and maxillofacial surgeons noted the complementary effects of propofol and ketamine.^{40–43} Soon articles began to appear in

both the medical and the oral and maxillofacial surgery literature advocating the administration of low-dose ketamine with propofol. Another modification of the conventional “balanced cocktail” in some offices has been the replacement of fentanyl with remifentanyl.^{44,45} The latter is rapidly metabolized by esterases found in plasma, red blood cells (RBCs), and interstitial tissues, which enables rapid emergence to accompany an excellent level of intraoperative analgesia.

Training, professional organizations, and standards

During the early years training in surgery and anesthesia for oral surgeons was largely by preceptorship and no professional organizations existed. However, as the field of exodontia began to emerge from the parent dental profession, it became obvious to those practicing exodontia that they should establish an organization of their own. In 1918, after 3 years of preparation, the charter meeting of the American Society of Exodontists was held in Chicago. Over the years, the name of the organization evolved from the American Society of Exodontists to the American Society of Oral Surgeons and Exodontists and in 1943 the American Society of Oral Surgeons (ASOS). The latter name was to be kept until 1978 when the organization took its current name, the American Association of Oral and Maxillofacial Surgeons (AAOMS).⁴⁶

As discussed above, during the early part of the 20th century anesthesia was administered by nurse anesthetists rather than anesthesiologists.¹⁸ Consequently, oral surgeons obtained their training through anesthesia training programs which were run by nurse anesthetists. Gradually anesthesiology became an accepted specialty of medicine and university-based anesthesia departments began to appear in the late 1920s and 1930s.⁴⁷ By the 1940s formal oral surgery training programs had also become established, and oral surgeons were able to receive anesthesia training through the departments of anesthesiology.

Since it was apparent that anesthesia played such a critical role in dental practice, the American Dental Society of Anesthesiology (ADSA) was established in 1954.⁴⁸ Many of its initial members were prominent oral surgeons, and oral and maxillofacial surgeons continue to constitute the majority of the membership of the organization. The ADSA publishes its own periodical, *Anesthesia Progress*, and conducts continuing education programs on various aspects of anesthesia as it relates to both oral and maxillofacial surgery and dentistry in general.

Oral surgery educators and the leaders of the ASOS developed a close working relationship that led to the conference on Anesthesia for the Ambulatory Patient which was held in Chicago in 1966. This conference initiated discussion on the scope of training required for competent delivery of

anesthesia in an office setting.¹¹ The dialog culminated in an increase in the requirement for general anesthesia training from 3 to 6 months. The latter requirement was definitively recorded in the ASOS document “Essentials of An Advanced Educational Program in Oral Surgery”.

Fortunately for the members of the specialty, its leaders have often been farsighted individuals who have assured maintenance of high standards. Rather than wait for legislative mandates which might place unreasonable demands on its membership, the association and its component chapters have established anesthesia standards for the profession. The keystone to these efforts has been in the realm of self-regulation. In 1967 under the leadership of Dr Frank McCarthy and Dr Howard Davis, the Southern California Society of Oral Surgeons instituted a voluntary office anesthesia evaluation program.^{11,37} By 1970 the Office Anesthesia Evaluation became a requirement for membership in the society. In keeping with the concept of a competent anesthesia team for office-based surgery, these same surgeons in California developed a training program for surgical assistants. In 1971 the ASOS followed the lead of the California Society and added the office anesthesia evaluation to its national program. This was ultimately followed by an anesthesia assistant training program as well.

In 1970 a liaison committee consisting of the ASOS, the ADSA, the ADA (American Dental Association), and the ASA (American Society of Anesthesiologists) was formed.^{11,48} This assured continued training of dentists in anesthesia residency training programs. True to the path of training established by the liaison committee, current oral and maxillofacial surgery residents train side by side with anesthesiology residents in university and hospital training programs throughout the US.

An important affiliation in maintaining high standards in the delivery of anesthesia services by oral and maxillofacial surgeons has been the close relationship which exists between the AAOMS and the ASA. To ensure that guidelines for safe anesthesia practice are consistent, the ASA reviews both the *Office Anesthesia Evaluation Manual*⁴⁹ and the *Parameters of Care*⁵⁰ document published by AAOMS.

To ensure the effectiveness of the efforts of OMFS training programs, continuing education programs, and the office anesthesia evaluation program, AAOMS maintains an Outcomes Committee. In 2003 the committee conducted the most extensive study of office-based ambulatory anesthesia ever reported.⁵¹ The study found that “95% of the time the operating surgeon is the anesthetist and performs the operation with a support team of at least 2–3 individuals and monitoring techniques”. The study reported a safety record which was unexcelled and a high level of patient acceptance. Another recent study of nearly 50 000 anesthetics supported the concept of the opera-

tor-anesthetist model. The study concluded there was “no statistically significant difference in complication rates between anesthesia administered by an OMS functioning as an anesthetist–surgeon and anesthesia administered by an anesthesiologist”.⁵² Smaller studies from Massachusetts,⁵³ a residency training program,⁵⁴ and a private office setting⁵⁵ all point to equally low or lower complication rates in the operator-anesthetist setting.

Safety frequently goes hand-in-hand with quality and patient satisfaction.⁵⁶ In a study of over 34 000 OMFS patients Coyle⁵⁷ concluded that the patients were overwhelmingly satisfied with deep sedation and general anesthesia provided in the oral and maxillofacial surgery office-based ambulatory setting. Patient dissatisfaction was most closely related to anxiety, pain, vomiting, and awareness during surgery. The low incidence of these undesirable effects was responsible for the high levels of patient acceptance of office-based anesthesia in oral and maxillofacial surgery. These findings are consistent with those reported in other types of ambulatory anesthesia.⁵⁸

Goals and objectives in the administration of anesthesia

The initial intuitively derived concepts

Early on, both those who administered anesthesia and the patients who received it, established intuitively derived requisites for an anesthetic. The essential requisite of lack of toxicity was derived from experience with chloroform, while that of non-flammability was fostered by fires and explosions caused by ether. Other characteristics would ultimately find a place in the works of John Lundy when he published his papers on balanced anesthesia in the 1920s,^{23,59} three quarters of a century after the discovery of the anesthetic properties of nitrous oxide and ether. These essential characteristics included: (1) satisfactory analgesia, such that the patient experienced no pain associated with the surgical procedure; (2) a state of relaxation such that the patient would remain immobile during the procedure and exhibit relaxed muscle tone; (3) lack of awareness and amnesia to the surgical event; (4) loss of consciousness or hypnosis. When all of these requisites were not met, the anesthetic was considered a failure, as was the case in Wells’ demonstration of nitrous oxide at Massachusetts General Hospital in 1844.

Throughout the history of anesthesia patient acceptance has been a primary moving force in the development of improved and safer anesthetic techniques. On 28 January 1848, within weeks of Simpson’s successful demonstration of chloroform anesthesia, a young woman, Hannah Greener, died following chloroform anesthesia.^{60,61} Word soon spread round the world. This generated such fear

that some soldiers in the Northern army during the America Civil War declined anesthesia altogether rather than undergo anesthesia with chloroform.^{6,7} Similarly, patients were frightened of the flammability of ether, and dreaded its foul smell and the frequent nausea which patients experienced post-operatively. Consequently, the list of requisites for the ideal anesthetic began to grow almost immediately after the inception of anesthesia.

The initial approach

For the better part of the 150 years since the discovery of surgical anesthesia in the 19th century, a mono-anesthetic agent was sought. It was hoped that this agent would possess the full complement of the desirable characteristics discussed above. Several inhalation agents were investigated in the late 19th century and early 20th century in an attempt to find a single ideal agent which possessed the desired properties.² However, Lundy's work in the 1920s gave birth to a whole new concept: that there was in fact no ideal single agent and that multiple agents at lower doses could be administered to achieve the desired characteristics of the anesthetic.⁶² Furthermore, since the agents were given at lower doses, their side-effects could be minimized. As the 20th century progressed, the newer agents such as the benzodiazepines and the new narcotics were added to smooth the barbiturate-based intravenous anesthetic, providing validity to Lundy's concepts which were proffered well before their time.

Requisites for the ideal anesthetic in the modern era

In the modern practice of oral and maxillofacial surgery the original requisites for an anesthetic have been joined by a host of other attributes that are considered desirable in an anesthetic.^{58,63-65} Meeting these objectives not only provides a safe, but also a comfortable, anesthetic experience for patients as well. Many of these objectives have been derived from patient surveys to determine which outcomes are important to avoid.⁶⁶ These objectives include:

1. Maintenance of the body's homeostatic mechanisms.
2. Rapid onset and recovery.
3. Freedom from postoperative nausea and vomiting.
4. A feeling of well-being on emergence (postoperative euphoria).
5. A technique which can be used in medically compromised patients.
6. A technique which can be easily adapted for use in children and seniors.
7. A technique which retains sufficient pharyngeal and laryngeal reflexes to prevent aspiration, but not to predispose to laryngospasm.

8. Capable of being administered easily with familiar anesthetic equipment and supplies.
9. A technique well documented in the anesthesia literature and consistent with techniques currently in use by anesthesiologists.
10. A technique which is cost effective.

The essential role of the basic sciences in the advancement of anesthesia

Attempts to arrive at an ideal anesthetic in early years were thwarted by a lack of understanding of the areas of the CNS in which anesthetics exert their effects and how those effects are expressed. Initially anesthetic investigation was conducted on a purely empirical basis, i.e. subjects were given anesthetics, and the effects observed and recorded. As we have seen, often the first subject was, indeed, the investigator himself. Once an agent had been demonstrated to have efficacy, means were found to manufacture the agent, and it was then marketed. In the modern era research and development is often economically motivated. Large pharmaceutical corporations conduct research, or fund research at an academic institution, in order to identify agents which will ultimately provide a profit for the corporation. Regardless of the economic motivation, pharmaceutical research has led to a greater understanding of the nervous system, which in turn guides the search for new and improved anesthetic agents.

Areas of the brain affected by anesthetic agents

In the previous section we reviewed the extensive list of characteristics which are today considered essential in an anesthetic agent. An investigator attempting to identify such agents must have an appreciation of the multiple areas of the brain which are affected by anesthetics.⁶⁷ We will now examine some of the principal areas in which anesthetics exert their activity. The anesthetist must understand where these agents work to effectively provide a truly "balanced" anesthetic. Agents and dosages must be tailored to the individual case to provide an optimal anesthetic which is neither too light nor too deep. Too much of one or more agents can lead to a level of depression which can prolong recovery and compromise homeostatic mechanisms for respiration and cardiovascular stability. On the other hand, inappropriately chosen agents and low dosages may lead to an anesthetic that is so "light" that the patient is overly aware of the surgery.⁶⁸

The limbic system and the centers for memory

Emotion and memory are intimately related, and it is difficult to discuss one without consideration of the

other.^{69,70} Emotion exerts a powerful influence on what we notice and remember. We tend to recall more clearly those events which are related to strong feelings such as pain and unhappiness on the one hand, and joy and pleasure on the other. In providing anesthesia we must deal with the patient's emotionally imprinted memory "baggage" preoperatively and hope to imprint less unpleasant memories postoperatively.

The term "limbic" (Latin for rim) was originally given to the rim of brain tissue surrounding the brainstem (Fig. 6b.5) in the works of Willis in 1667.⁷¹ In the 1850s, Paul Broca defined the limbic lobe with two of its more prominent components, the cingulate gyrus and parahippocampal gyrus and a number of associated nuclei. Initially these areas of the brain were thought to be related to the sense of smell. However, in the 1930s Papez speculated that the function of these structures was related to emotion.⁷² He suggested various pathways amongst the nuclei which ultimately became termed the "Papez circuit". At about the same time that Papez was developing his theories, Heinrich Klüver and Paul Bucy removed the medial aspect of the temporal lobe in Rhesus monkeys, thereby destroying much of the limbic system. The animals developed hyperactivity and hyper-

sexuality and demonstrated marked changes in emotional behavior.⁷³ Over the years, investigators such as MacLean in the 1970s and Nauta and Domenick in the 1980s extended the areas thought to be involved in emotion to adjacent cortical and thalamic locations and the amygdala.^(71,74-76) The latter important structure was studied by John Downer at the University College in London in the 1950s and appears to control aggressive behavior and mediate the neuroprocesses which invest sensory experience with emotional significance.⁷⁷

In view of the various areas of the brain which are involved in emotion, some current authors feel that the term "limbic system" as a characterization for the brain's emotional processes is archaic. They feel that multiple systems are involved and that alternative terms should be developed.^{78,79} However, to date, no one has proposed a universally accepted term. Regardless of whether there is a single limbic system or multiple systems involved in emotion, human emotional response represents a spectrum ranging from calm and placidity at one end and anxiety, aggression, and rage at the other. From an anesthetic standpoint, the pharmacologic category of drugs which most profoundly affects this system (or systems) is the benzodiazepines.

Fig. 6b.5 Modern conception of the limbic system. Especially important components of the limbic systems not emphasized in early anatomical accounts are the orbital and medial prefrontal cortex and the amygdala. These telencephalic regions, together with related structures in the thalamus, hypothalamus, and ventral striatum, are especially important in the experience and expression of emotion (green). Other parts of the limbic system, including the hippocampus and the mammillary bodies of the hypothalamus, are no longer considered important neural centers for processing emotion (blue). (Reproduced from *Neuroscience*, 4th edn. Sunderland, MA: Sinauer Associates, 2008; 741, Fig. 29.4 by permission. Copyright © 2008 Sinauer Associates Inc.)

Fig. 6b.6 Brain areas which are thought to give rise to declarative memory. Of primary importance is the hippocampus which is in close approximation and has multiple connections with the amygdala. (Reproduced from *Neuroscience*, 4th edn. Sunderland, MA: Sinauer Associates, 2008; 800, Fig. 31.7 by permission. Copyright © 2008 Sinauer Associates Inc.)

Similar to emotion, memory involves multiple brain areas (Fig. 6b.6).⁸⁰ One of the primary amongst these is the hippocampus, which is in close approximation and has multiple connections with the amygdala. It has been recently demonstrated that extra synaptic alpha-5 GABA_A receptors in the hippocampus are vital to the amnesia-inducing effects of certain general anesthetics. It currently appears that the amnesic effects of anesthetic agents involve circuits in the hippocampus, amygdala and rostral areas of the cortex which have been implicated in learning and memory.⁸¹ As discussed above, emotion markedly influences memory, and it is not surprising that the pharmacologic agents which have greatest influence on emotion, also tend to affect memory, and therefore amnesia, during anesthesia for surgery.⁸²

The “reticular activating system” and thalamus

From the time of the initial demonstration of surgical anesthesia by Wells and Morton, loss of consciousness has been considered the primary goal of anesthesia. Thus the casual observer would assume that a considerable body of research would have been conducted to better understand loss of consciousness. However, with the exception of the studies of Moruzzi and Magoun in the 1940s discussed below, there was little investigation of consciousness and wakefulness during the entire 20th century. Both George Mashour,⁴ an anesthesiologist, and John Searle,⁸³ a philosopher, have commented on the paucity of studies on consciousness during the 20th century. In their reviews of the literature, both have found that, for inexplicable reasons, consciousness lost legitimacy as a topic of serious inquiry.⁴ However, within the last decade of the century a landmark conference consisting of physicians, neuroscientists, cognitive scientists, philosophers, and physicists was convened to discuss the possibility of an interdisciplinary approach to the study of consciousness. Soon numerous studies got under way, several of which are discussed below.

The term “reticular activating system” was proposed by Moruzzi and Magoun during their studies in the 1940s, and led to the concept that there might be a neural system in the midbrain and rostral pons that was responsible for wakefulness and its transition into sleep. The term has continued to be used since that time.^{84,85} However, once again, as in the case of emotion and memory, wakefulness does not appear to be controlled by a simple single “system”. Nonetheless, the reticular formation in the brainstem does appear to be a predominant component of “arousal”, presumably by its activation of various subcortical and cortical structures.^{86,87}

The reticular formation (Fig. 6b.7) is a somewhat loose group of cells that is spread from the brainstem to the thalamic area with a longitudinal orientation. Although originally described as being a “sparse network”, it contains a number of discreet nuclei and exhibits discreet neurochemical profiles.⁸⁶ Discharge rates within the neurons of the reticular formation have been correlated with arousal and active sleep by investigators such as Steriade *et al.*⁸⁸ However, the reticular formation also contains neurons which are responsible for muscle tone, nociception, and the control of breathing and the cardiovascular system. Consequently, the reticular formation is indeed complex, as opposed to the original concept of a “sparse network”.⁸⁵ Anesthetic agents which tend to exert their primary effects on the various centers for wakefulness are the barbiturates and propofol⁸⁹ amongst the intravenous agents and the halogenated hydrocarbons among the inhalation agents.

Consciousness is manifested in the cortex, and some studies, such as those by Velly *et al.*,^{90,91} suggest that the cortex itself may well be the main site of action of anesthetic agents in producing loss of consciousness. However, other investigators have proposed alternative mechanisms. An important structure in the path from the brainstem to the cerebral cortex is the thalamus⁸⁰ (see Fig. 6b.5). One theory as to the mechanism whereby anesthetics induce unconsciousness is the presence of a so-called “thalamocortical switch”

Fig. 6b.7 Brain areas which are thought to maintain consciousness. Consciousness appears to be dependent upon important interactions between the reticular formation and thalamocortical structures. (Reproduced from *Neuroscience*, 4th edn. Sunderland, MA: Sinauer Associates, 2008; 428, Fig. 17a by permission. Copyright © 2008 Sinauer Associates Inc.)

expounded by Alkire *et al.*⁹² Yet another study by John and Prichet⁹³ suggests that there may be an “anesthetic cascade” with a cascade of events leading to loss of consciousness. These include hyperpolarization of thalamic and cortical cell membranes, and suppression of arousal areas in the pons and midbrain. Regardless, it appears that there are important thalamic–cortical and brainstem interactions which are the most likely targets of anesthetic agents that render a patient unconscious.^{4,81,92,94–99}

Another important function of the thalamus is its relay function between sensory inputs and cortical perception.^{100,101} It is this relay which appears to be one of the primary targets of the dissociative anesthetic ketamine.⁶⁴ The patient enters a catatonic state in which he does not respond to sensory stimuli and remains motionless, apparently totally “dissociated” from his environment.³⁴

Central opioid receptor sites

Until the early 1970s, it was assumed that there was a single opioid receptor site in the CNS. However in 1973, radio ligand binding studies by three independent teams pointed to the presence of three types of opioid receptors. Each was given a Greek letter designation as follows: μ for the morphine type of receptor, κ for the ketocyclazocine type, and δ for the skf10047 (n-allylnormetazocine).¹⁰² The functions of the μ receptor are supraspinal and spinal analgesia, sedation, euphoria, slowing of gastrointestinal (GI) motility, inhibition of respiration, and modulation of hormone and neurotransmitter release.^{36,103} The δ subtype provides supraspinal and spinal anesthesia as well as modulation of hormone and transmitter release.¹⁰² Finally, the κ subtype, in addition to providing supraspinal and spinal analgesia, causes psychotomimetic affects and slows GI motility.¹⁰⁴

Until the late 1980s opioids were believed to exert their effects only centrally. However, we now know

that there are three levels at which they have activity: supraspinal sites, spinal sites, and peripheral sites.¹⁰⁵ In addition, there are two pathways along which there are sites at which opioids exert their affects. The first of these is the traditional afferent pain transmission pathway. Sites of action along this pathway include: (1) a direct action on inflamed or damaged peripheral tissues; (2) inhibition in the spinal cord;^{36,106} (3) probable central site in the ventrolateral aspect of the thalamus (Fig. 6b.8). The action of opioids at these spinal

Fig. 6b.8 Putative sites of action of opioid analgesics on the afferent pain transmission pathway from the periphery to the higher centers. A: Direct action of opioids on inflamed or damaged peripheral tissues. B: Inhibition also occurs in the spinal cord. C: Possible sites of action in the thalamus. Fig. 6b.9 Action of opioids at spinal sites, mu: (μ), kappa (κ), and delta (δ) agonists reduce neurotransmitter release from the pre-synaptic terminals of nociceptive primary afferents. Mu agonists also hyperpolarize second-order pain transmission neurons by increasing K^+ conductance, evoking an inhibitory postsynaptic potential. (Reproduced from *Basic and Clinical Pharmacology* (Katzung BG, ed.), 10th edn. New York: McGraw Hill, 2007. With permission of the McGraw-Hill Companies.)

sites is illustrated in Fig. 6b.9. There is also a descending pathway (Fig. 6b.10) along which opioids exert their effects on pain-modulating neurons within the: (1) midbrain periaqueductal gray area;¹⁰² (2) the rostral ventral medulla; (3) the locus caeruleus. This indirectly controls pain transmission pathways by enhancing inhibition to the dorsal horn (Fig. 6b.11).¹⁰⁵

The vital centers and homeostatic receptor mechanisms

Most anesthetic agents and narcotics exert depressive effects on the body's normal homeostatic mechanisms for respiration and circulation. For instance, in the case of opioids there is dose-dependent depression of the ventilatory response to hypercapnia and hypoxia due to opioid action on the μ_2 receptors in the respiratory centers of the medulla.¹⁰⁵ In the case of propofol, there is a 50% reduction in ventilatory response to carbon dioxide and decrease in the acute ventilatory response to isocapnic hypoxia.¹⁰⁷ In addition, the

autonomic cardiovascular centers in the medulla are depressed by most anesthetics, leading to a loss of sympathetic vascular tone. The resulting vasodilation tends to cause hypotension.¹⁰⁶ This is true for almost all anesthetic agents except ketamine, which tends to cause a sympathetic response that leads to hypertension.³⁴

The critical realization that on a molecular basis all anesthetic drugs share a common mechanism of action

At the beginning of the 20th century Hans Meyer and Charles Ernest Overton^{108–110} made the observation that a wide spectrum of chemically dissimilar agents could produce general anesthesia. Furthermore, they determined that the potencies of the general anesthetics available at that time correlated well with their water/oil partition coefficient. These "lipid theories"

Fig. 6b.10 Opioid analgesic action on the descending inhibitory pathways. Sites of action on pain-modulated neurons in the mid-brain and medulla including the midbrain periaqueductal gray area (A), rostral ventral medulla (B), and the locus ceruleus indirectly control pain transmission pathways by enhancing descending inhibition to the dorsal horn (C). (Reproduced from *Basic and Clinical Pharmacology* (Katzung BG, ed.), 10th edn. New York: McGraw Hill, 2007. With permission of the McGraw-Hill Companies.)

were developed into the concept that anesthetic agents had a common non-specific mechanism. They theorized that the agents dissolve in the membrane of neurons and bring about a physical change such as thickening of the membrane. These changes were felt to alter membrane permeability to ions which then led to the anesthetic effect. The idea presented by Meyer and Overton was so convincing that it was looked upon as the primary mechanism of anesthesia for three quarters of a century. It was not until the closing decades of the century that Franks and Lieb¹¹¹⁻¹¹³ convincingly demonstrated that the actual mechanism behind ion flux was the action of general anesthetics on proteins that leads to opening and closing (or blocking) of ion channels in the nerve membrane. Thus the basic sciences have led to a critical realization in that it appears that on a molecular basis all inhalation and intravenous anesthetic agents share a common mechanism of action: they affect the movement of ions through ion channels in neuronal membranes.^{81,108,115-116} Consequently, one's understanding of the mechanism of action of anesthetics is dependent upon an appreciation of the elegant mechanism by which nerve impulses are transmitted through the nervous system.

Nerve impulse transmission is based on the movement of ions such as Na^+ , Cl^- and K^+ through channels in the neuronal membrane. Control of this movement takes place in one of four ways (see Fig. 6b.12).^{98,117}

Fig. 6b.11 Modulating affect of descending pathways by μ opioid receptor mediated analgesia. Opioids inhibit an inhibitory GABAergic interneuron resulting in enhanced inhibition of nociceptive processing in the dorsal horn. 1. In voltage-gated channels, control is through a voltage sensor component of the protein.
2. In ligand-gated channels, control is through the binding of a neurotransmitter substance to the channel receptor (ionotropic receptors).
3. In G protein-coupled (metabotropic) channels a neurotransmitter activates an intermediary protein, the G protein, which in turn interacts directly with the ion channel.
4. In diffusible second-messenger metabotropic ions channels the neurotransmitter activates a G protein which then activates an enzyme. The activated enzyme generates a diffusible second messenger which interacts with ion channels.

It was originally thought that the action of anesthetics was due to their effects on ligand-gated channels. However, it has now been demonstrated that voltage-

Fig. 6b.12 Types of ion channels and neurotransmitter receptors in the CNS. (a) Voltage-gated channel in which a voltage sensor component of the protein controls the gating (broken arrow) of the channel. (b) Ligand-gated channel in which binding of the neurotransmitter to the ionotropic channel receptor controls the gating (broken arrow) of the channel. (c) A G protein-coupled (metabotropic) receptor, which when bound, activates a G protein that in turn interacts directly with the ion channel. (d) A G protein-coupled receptor, which when bound, activates a G protein that activates an enzyme. The activated enzyme generates a diffusible second messenger such as cAMP, which interacts with the ion channel. (Reproduced from *Basic and Clinical Pharmacology* (Katzung BG, ed.), 10th edn. New York: McGraw Hill, 2007. With permission of the McGraw-Hill Companies.)

gated sodium channels, as well as calcium channels, are also affected by anesthetic agents.

Transmission of the action potential along the axon

The mechanism of action potential propagation is illustrated in Fig. 6b.13. A depolarizing stimulus on the axon opens the voltage-sensitive sodium channels in the region.¹¹⁷ The open channels allow passage of ions into the neurons.^{98,118} This results in depolarization of the membrane potential that generates an action potential. The local current flow depolarizes the membrane potential in the adjacent region that leads to opening of the sodium channels in the neigh-

boring membrane. This local depolarization triggers an action potential in this region as well, which then spreads in a continuing cycle to the end of the axon.^{118–120}

Impulse transmission through the synapse

When the action potential reaches the synapse, voltage-sensitive calcium channels are activated in the membrane of the terminal bouton (Fig. 6b.14). The calcium flowing into the terminal promotes the fusion of synaptic vesicles with the presynaptic membrane.¹²¹ Neurotransmitter substances contained in the vesicles are released into the synaptic cleft and diffuse to the receptors on the postsynaptic mem-

Fig. 6b.13 Action potential conduction requires both active and passive current flow. Depolarization opens Na⁺ channels locally and produces an action potential at point A of the axon (time $t = 1$ above). The resulting inward current flows passively along the axon, depolarizing the adjacent region (point B) of the axon. At time 2 ($t = 2$) the depolarization of the adjacent membrane has opened Na⁺ channels at point B. This results in the initiation of the action potential at this site and additional inward current that again spreads passively to an adjacent point (point C) farther along the axon. The cycle continues along the full length of the axon. As the action potential spreads, the membrane potential repolarizes due to K⁺ channel opening and Na⁺ channel inactivation. This creates a "wake" behind the action potential during which the axon is temporarily refractory to depolarization. The latter prevents backward propagation of the impulse (time 4 above). (Reproduced from *Neuroscience*, 4th edn. Sunderland, MA: Sinauer Associates, 2008; 55, Fig. 3.12 by permission. Copyright © 2008 Sinauer Associates Inc.)

brane.¹¹⁷ When the transmitters bind to their receptive sites, there is a brief change of membrane conduction in the postsynaptic cell. This leads to an increase in sodium and potassium permeability which enables impulse conduction through the postsynaptic neuron. Virtually all of the drugs that act in the CNS produce their effects by modifying one of the steps in chemical synaptic transmission.¹¹⁷ In the postsynaptic region the transmitter receptor provides the primary site of drug action. However, it now appears that there are extra-synaptic receptors as well.^{81,122}

Neurotransmitter substances which enable transmission of the impulse from one neuron to the next

GABA_A receptor

As we have seen, virtually all anesthetic agents exert their action on ligand-gated ion channels. Gamma

amino butyric acid (GABA_A) is the most important inhibitory neurotransmitter in the mammalian CNS.¹²³ As many as one third of all synapses in the CNS are GABAergic.¹²⁴ The GABA_A receptor (Fig. 6b.15) is a member of a super family of ligand-gated ion channels that include the nicotinic acetylcholine receptor, the 5-hydroxytryptamine type 3 receptor (5HT₃), and the glycine receptor.¹²⁵ The GABA_A receptor has a pentameric structure assembled from five subunits (Fig 6b.15).¹²⁶ The most common combination of subunits is two α sub-units, two β subunits, and one γ subunit. Activation of GABA receptors has been shown to initiate an influx of chloride ions which leads to hyperpolarization of the nerve membrane. This blunts excitatory input and reduces the excitability of the affected neurons.¹²⁴

Neurons which contain GABA receptors are found throughout the brain, including the cortex, the basal forebrain, the thalamus, the hypothalamus, and the brainstem. During non-rapid eye movement (NREM)

Fig. 6b.14 (a) A GABAergic synapse. Calcium flowing into the terminal promotes fusion of the synaptic vesicles with the presynaptic membrane. Neurotransmitter substances are released from the vesicles into the synaptic cleft and diffuse to the receptors on the postsynaptic membrane. When the transmitters bind to the receptor sites, there is a brief change of membrane conduction in the postsynaptic cell. On the cytoplasmic side these channels are directly linked to the anchoring protein gephyrin. (b) GABA_A binding sites of the GABA_A receptor. In addition to the binding sites for the physiologic transmitter GABA, the receptor has modulatory binding sites for a number of anesthetic agents such as the benzodiazepines, barbiturates, propofol and inhalation agents, as well as halogenated inhalation agents. (Reproduced from *Anesthetic Pharmacology: Physiologic Principles and Clinical Practice* (Evers SA, Maze M, eds.). Philadelphia, PA: Churchill Livingstone, 2004; 418, Fig. 25-2 by permission.)

Fig. 6b.15 The GABA_A receptor has a pentameric structure assembled from five subunits: two α subunits, two β subunits and one γ subunit. Activation of the receptor initiates influx of chloride ion which leads to hyperpolarization of the nerve membrane. (Reproduced from *Miller's Anesthesia* (Miller RD, ed.), 6th edn. New York: Elsevier/Churchill Livingstone, 2005; 337, Fig. 10-14 by permission. Copyright © 2005 Elsevier.)

sleep GABA is released into the cerebral cortex in the highest concentration.¹²⁷

A large number of agents target the GABA_A receptor. These include the benzodiazepines, propofol, barbiturates, inhalation anesthetics, and ethanol (Fig. 6b.14b).¹²⁸ The most extensively studied of the drugs which interact with the GABA_A receptor are the benzodiazepines.^{127,129} The classic bioaffinity benzodiazepine binding site is located between the α_1 and γ_2 subunits.¹³⁰ However, there are a number of subtypes of α , β and γ receptor subunits. The various actions of the benzodiazepines appear to be mediated by different receptor subtypes. For instance, the sedative action appears to be mediated by the α_1 receptor while the anxiolytic action is mediated by α_2 , α_4 , and γ_5 receptors.¹²⁷ Anterograde amnesia and anticonvulsant properties seem to be mediated through α_1 receptors and anxiolysis and muscle relaxation by α_2 receptors.¹³¹

Propofol can be used for either sedation or for general anesthesia. For intravenous anesthetic agents it appears that loss of consciousness is mediated purely through β_3 -containing receptors while β_2 subunit receptors mediate the sedative properties of these anesthetics.¹³² Several studies suggest the β subunit M₃ segment is the binding site for propofol's direct anesthetic action.¹³³

It was initially thought that all GABA_A receptors were located in synapses. However, more recent evidence indicates that there may be extra-synaptic GABA_A receptors as well.¹²⁴ These appear to be sensitive to low concentrations of anesthetics and contain an $\alpha 5$ subunit which most synaptic receptors lack.¹²²

The NMDA receptor and glutamate

Glutamate is the main excitatory transmitter in the brain and the spinal cord. Approximately 75% of the excitatory transmission of the brain is due to glutamate.¹¹⁸ One of its ionotropic receptors is the NMDA or N-methyl-D-aspartate receptor (Fig. 6b.16).^{134,117} The ion channel is permeable to calcium, as well as sodium and potassium to a lesser extent.¹³⁴ Like the GABA_A receptor the NMDA receptor is a pentameric structure for which six subunits have been identified. Simple binding of glutamate does not open the channel. Glycine is a co-transmitter and the channel is normally blocked by Mg²⁺ ion.^{118,135} Consequently, the neuron must be strongly depolarized so that the Mg²⁺ ion is expelled before the channel opens.^{117,118}

The NMDA receptor contains several binding sites. Glutamate and glycine have separate binding sites, while the recreational hallucinogen phencyclidine and the dissociative anesthetic ketamine, have yet another binding site inside the channel.¹¹⁸

Other pertinent receptors

Other neurotransmitters modulate ligand-gated ion channels that are affected by anesthetic agents, presumably to a lesser extent than do the GABA_A and NMDA receptors. For instance, ketamine appears to

Fig. 6b.16 The NMDA receptor is a pentameric structure for which six subunits have been identified. Channel opening also depends upon the co-transmitter glycine as well as expulsion of Mg²⁺ ion by depolarization of the neuron. (Reproduced from Kohrs R, Durieux ME. Ketamine: teaching an old drug new tricks. *Anesth Analg* 1998; 87: 1186–93 by permission. Copyright © 1998 Lippincott Williams & Wilkins.)

be a potent inhibitor of the central nicotinic acetylcholine receptor (nAChR).¹³⁶ Agents like ketamine which inhibit nAChR have analgesic effects at subanesthetic concentrations, while those which do not, such as etomidate and propofol, possess no analgesic activity. Since nicotinic acetylcholine receptors are sensitive to ketamine, this interaction may be in part responsible for the dissociative and analgesic properties of ketamine. However, overall the contribution of acetylcholine activity to general anesthesia is less clearly defined than that of GABA_A and NMDA receptors.¹³⁷

Yet another neurotransmitter which may be affected by anesthetics is the glycine receptor.¹²³ Compared to the GABA_A receptor the glycine receptor has a very modest pharmacologic profile. Currently there are no therapeutically useful ligands that act at the glycine receptor site, despite its pivotal role in providing innervation in the brainstem and spinal cord.

Classification of anesthetics on the basis of molecular targets

As we have seen, all general anesthetic and sedative agents do not have the same molecular target. Solt and Forman¹³⁸ have proposed a classification of anesthetic agents based on their molecular targets. Their classification is illustrated in Table 6b.1.

Multiple sites of action and receptors in the CNS dictate a balanced approach

Because multiple receptors in the CNS are involved in anesthesia, there is no currently available single agent which interacts with all of the appropriate

Table 6b.1 Anesthetic classification based on clinical features and molecular targets. (Modified from: Solt K, Forman SA. Correlating the clinical actions and molecular mechanisms of general anesthetics. *Curr Opin Anaesthesiol* 2007; 20(4): 300–6, by permission. Copyright © 2007 Lippincott Williams & Wilkins.)

	Group 1	Group 2	Group 3
Anesthetic agents	Propofol, etomidate, barbiturates	Nitrous oxide, ketamine	Halogenated agents
Clinical features	Strong hypnotics, strong amnestics	Weak hypnotics, potent analgesics	Strong hypnotics, strong amnestics
Molecular targets	GABA _A receptor	NMDA, nCAhR receptors	GABA _A , glycine, glutamate, and nAChR receptors

receptors. In addition, it is highly unlikely on a statistical basis that a monoanesthetic agent could ever be developed that would provide the interaction with all the desired receptors. Interestingly the empirically derived approach of using a balanced anesthetic is consistent with what is currently known about anesthetic agents from a scientific standpoint. Consequently, when anesthesiologists and anesthesiologists seek to develop an anesthetic approach for outpatient surgery, multiple agents must be used with a balance of their various characteristics. In many cases, it is not sufficient to merely balance such primary characteristics as hypnosis and dissociation. Often the so-called “side-effects” must be balanced as well. This will often negate the untoward influence of those side effects.¹³⁹

The current status of office anesthesia in the oral and maxillofacial surgery practice

The maintenance of high anesthesia standards for the administration of anesthesia in oral and maxillofacial surgery has enabled oral and maxillofacial surgeons to provide a wide range of outpatient anesthesia services for their patients. The vast majority of procedures performed by members of the specialty can be treated with anesthesia administered by the operator–anesthetist.⁵² This includes anesthesia for ASA I, II, and low-level ASA III patients. For high-level ASA III patients and ASA IV patients, treatment is best performed in an outpatient surgery center or hospital setting with a separate anesthesiologist or anesthetist.¹⁴⁰

What enables the delivery of safe and comfortable anesthesia for patients in a modern office setting is the maturing perspective on the nature of the anesthesia (as discussed above). During the late decades of the 20th century and the first decade of the 21st century advances in basic science have provided a far more complete understanding of where and how anesthetics work in the CNS. This has in turn led to the development of anesthetic techniques combining multiple agents that make it possible for surgeons to perform procedures in their offices which heretofore could only be performed in a hospital. Historically an empirical approach has been used to select those agents which appeared to have more desirable characteristics than their predecessors. In this section we will explore the currently preferred agents. Although

the majority of surgeons prefer using the agents listed, the list is not intended to be exhaustive. There are surgeons who continue to use some of the “older” agents and techniques to provide a safe and comfortable anesthetic experience for their patients. We will examine the primary anesthetic agents propofol and ketamine, as well as the various ancillary agents which are used, including anxiolytics, narcotics, and anticholinergics.

Primary anesthetic agents

Propofol

Until the waning decades of the 20th century, ultra-short-acting barbiturate anesthetics such as thiopental and methohexital reigned supreme as the intravenous agents of choice in hospital operating rooms, outpatient surgery centers and oral and maxillofacial surgery offices. However, during the 1970s work began on a new family of anesthetic agents that in a relatively short period of time would surpass the daunting popularity of the barbiturates. By the end of the 1970s and the beginning of the early 1980s one of these agents was ready for release and reports began to appear in the literature. In 1977 Kay and Rolly¹⁴¹ reported on the first clinical trials, and in 1980 James and Glen³⁸ reviewed the research that had resulted in the development of an intriguing new agent, 2,6-diisopropylphenol, or propofol. It provided rapid onset and recovery, a “smooth” intraoperative course with stable operating conditions, as well as antiemetic and postanesthetic euphoric qualities.¹⁴² Over the next 25 years propofol would not only replace thiopental and methohexital, it would revolutionize the practice of outpatient anesthesia as well.

Propofol formulation

Propofol is a substituted phenol (2,6-diisopropylphenol) which belongs to a family termed “hindered phenols” (Fig. 6b.17).³⁸ It is insoluble in water and must be mixed with other agents to make it suitable for injection into the bloodstream. The initial propofol formulation was with Cremophor EL, but it had to be abandoned because of anaphylactoid reactions.^{34,143,144} Cremophor was replaced with an intralipid mixture similar to that which had been used for total parenteral nutrition. This resulted in a 1% aqueous emulsion in a vehicle that includes 10% soybean oil, 2.25% glycerol and 1.25% purified egg lecithin. This mixture

Fig. 6b.17 Propofol (2,6-diisopropylphenol). (Reproduced from *Clinical Anesthesiology* (Morgan GE, Mikhail M, Murray M, eds.), 4th edn. New York: McGraw-Hill, 2006. With permission of the McGraw-Hill Companies.)

is perishable, which necessitated the inclusion of preservatives.^{143,145} The first of these was EDTA employed by AstraZeneca. A less expensive formulation utilizing sulfites was introduced by Baxter, but sulfite allergy proved to be a problem with this formulation.¹⁴⁶ Ultimately benzyl alcohol, which had a time-honored track record as a preservative in other pharmaceuticals, was added by several manufacturers of generic products.¹⁴⁷ The expense of the initial propofol formulations limited its acceptance to some extent, but this problem has been overcome with the newer, far less expensive formulations.

Although improvements in the formulation have reduced the problem of water insolubility, they have not totally eliminated it. Consequently, considerable pharmacologic research has centered on developing water-soluble propofol-like drugs.¹⁴⁸ These have now become a reality and are discussed in the final section of the chapter, Future trends and advancements – on the horizon.

Mechanism of action

Like most intravenous anesthetic agents, propofol exerts its effects by positive modulation of the inhibitory function of GABA on the GABA_A receptor.³⁴ At lower concentrations, such as those used for sedation, propofol appears to facilitate the action of GABA in enhancing chloride conductance and hyperpolarization of the postsynaptic membrane. However, at higher concentrations, such as those used for general anesthesia, propofol directly activates chloride-channel opening (see Fig. 6b.14). Like barbiturates, propofol has a different receptor site from the benzodiazepine receptor site.¹⁴⁹ In addition to its primary activity on the GABA receptor, propofol is active at glycine activated chloride channels, nicotinic acetylcholine receptors, and some excitatory glutamate receptors.¹⁴⁵

Propofol exerts its activity in several areas within the brain, including the traditional reticular activating system (or “systems” as previously discussed). Some of its sedative effects are due to its action on GABA receptors in the hippocampus which results in inhibition of acetylcholine release within both the hippocampus and prefrontal cortex.¹⁵⁰ There is also widespread inhibition of NMDA glutamate receptors with modulation of sodium channel gating.¹⁵¹ In addition to its effects within the brain, there are also direct depressant effects on the neurons of the spinal cord due to action at GABA_A and glycine receptors.^{151,152}

Two interesting CNS actions of propofol which have led to its widespread popularity are a postoperative sense of well-being and its antiemetic effects. The former may be related to the increase in dopamine concentration in the nucleus accumbens which follows propofol administration.¹⁵³ This is a phenomenon similar to that which has been found to play a role in the euphoric effects of recreational drugs and drugs of abuse. Propofol’s antiemetic action may be related to its diminution of serotonin levels in the area postrema.¹⁵⁴

Distribution

Propofol is highly lipid-soluble and is rapidly redistributed to peripheral compartments, including muscle, fat, and skin. When viewed from the standpoint of a three-compartment model, it has an initial distribution half-life of 1–8 minutes, a slow distribution half-life of 30–70 minutes, and an elimination half-life of 4–24 hours.^{34,145} Although there are several factors which affect redistribution, the major ones are age, gender, and body weight. These effects tend to create different distribution groups:

1. Children – the drug is very rapidly redistributed in younger patients who may require at least a 50% increase in drug dose on a weight-for-weight basis.^{155,156}
2. Older patients – in the latter decades of life there is an increasing impairment of redistribution with a commensurate increase in sensitivity to propofol.^{157,158}
3. Gender – the drug is more rapidly redistributed in women who may require 10–15% larger doses of the drug on a weight-for-weight basis.^{159–161}
4. The obese – redistribution is altered in obesity and dosing should be based on lean body mass as opposed to total body weight.^{162,163}

Biotransformation and elimination

Propofol is rapidly metabolized through conjugation in the liver at a rate approximately 10 times faster than thiopental.¹⁶⁴ Interestingly, the pharmacokinetics of the drug are not affected by moderate cirrhosis.¹⁰⁶ There is extrahepatic metabolism, some of which takes place in the lung.¹⁶⁵

Hepatic conjugation of propofol results in inactive metabolites which are rapidly eliminated by renal clearance and less than 1% of the drug is excreted unchanged in the urine.¹⁶⁴ Renal insufficiency, even chronic renal failure, does not appear to affect the clearance of the parent drug.^{106,166}

Effects on organ systems

The primary effect of propofol on the cardiovascular system is a decrease in arterial blood pressure.¹⁴⁵ Propofol does not appear to impair myocardial contractility,^{144,145} but appears to exert its effects by decreasing vascular resistance secondary to inhibition of sympathetic vasoconstrictor activity.¹⁶⁷

Vasodilation may be in part due to a direct effect on intracellular smooth muscle calcium flux and increased release of nitric oxide by the vascular endothelium.¹⁶⁸ With age, the problem is accentuated by blunting of the baroreceptor response.¹⁶⁹

Relatively large induction doses of 2–2.5 mg/kg can produce a reduction in systolic blood pressure of up to 25–40%.³⁴ However, far less dramatic decreases are seen at the lower induction doses which are usually used in oral and maxillofacial surgery offices.¹⁷⁰ In addition, the hypotensive effect is largely overcome by stimulation,⁶² such as injections of local anesthetic solutions. Overall, the factors that tend to exacerbate hypotension are excessively large bolus doses, rapid administration of boluses and advanced age of the patient.¹⁰⁶ Heart rate does not undergo a significant change after induction with propofol. Several studies have suggested that propofol resets the baroreflex and thus reduces the tachycardic response to hypotension.¹⁷¹ Mild bradycardia may be noted within the first 10 minutes of induction.¹⁶⁶

Like barbiturate intravenous anesthetics, propofol is a respiratory depressant which causes apnea after an inductive dose.^{106,144,172} It affects central chemoreceptor sensitivity, largely by reducing the ventilatory response to hypercapnia.³⁴ Usually the ventilatory response returns to normal within approximately 30 minutes following discontinuation of a propofol infusion.¹⁴⁵

Unlike intravenous barbiturate anesthetics, propofol induces bronchodilation which can decrease the incidence of intraoperative wheezing in patients with asthma and COPD.^{106,145,173} There is also diminution of upper airway reflexes^{174,175} sufficient to allow pharyngeal suctioning of secretions. This lack of hyperactive airway reflexes may also be responsible for the markedly low tendency for laryngospasms in patients undergoing propofol anesthesia,^{174,176} especially compared to anesthesia with methohexital.⁵²

In addition to its hypnotic effects, propofol has antiemetic^{172,177–182} and euphoric^{153,183} properties. Other CNS effects include a decrease in both intracranial pressure and cerebral blood flow.¹⁴⁵ Propofol appears to have anticonvulsive properties as well.¹⁴⁵ Ironically, a few cases of long-term postoperative seizures have been reported in patients anesthetized with propofol, but the mechanism has not been elucidated.^{166,184}

Several of the various attributes discussed above would suggest that propofol would be associated with a rapid and smooth recovery. This has been substantiated by a number of clinical series.^{143,185–189}

Complications and side-effects

Although propofol possesses many highly desirable characteristics as an anesthetic agent, it is associated with untoward reactions as well. Propofol-associated hypotension¹⁴⁶ was discussed above and can largely be overcome by control of dosing and stimulation.

Another common problem is pain on injection. However, a pretreatment dose of lidocaine as low as 0.1 mg/kg is usually effective in reducing the incidence of pain on injection.⁶⁵ It has also been demonstrated that 1 ml of ketamine (10 mg/ml), 30 seconds before administration of propofol will markedly reduce the incidence of pain during propofol injection.¹⁹⁰

The propofol emulsion vehicle can lead to potential complications due to the inclusion of food products in the formulation, namely soy bean oil and egg lecithin.¹⁹¹ Allergic responses to these components have been reported, albeit rarely. Patients who are allergic to eggs are usually allergic to the albumen in the egg white as opposed to the lecithin from the yolk which is used in the propofol emulsion.¹⁰⁶ Approximately two thirds of infants with egg allergy will become tolerant to eggs by 7 years of age.^{192,193} Although soy allergy is fairly common in infants, it is usually transient. The prevalence of soy allergy is estimated at 0.3–0.4%. Reactions are usually mild, although deaths due to soy allergy have been reported. Soy oil, which is the product used in the propofol emulsion, appears to not be allergenic in soybean-sensitive individuals.¹⁹⁴

As mentioned above, the original formulation of propofol with Cremophor was abandoned due to the high incidence of allergic reactions.^{34,143,144} With the current propofol emulsion, hypersensitivity reactions have been dramatically reduced and have been estimated to be approximately 1:80 000–100 000. This compares to 1:1600 to 1:7000 for methohexital and 1:2500 to 1:10 000 for penicillin.¹⁰⁷

The use of a sulfite preservative in propofol formulations can incorporate an additional risk for allergic response.^{146,195} The incidence of true sulfite allergy in the general population is estimated at 1:1000.¹⁹⁶ Even non-sulfite-sensitive patients with asthma have a high incidence of bronchospasm following a metabisulfite challenge. In addition, 5–10% of chronic asthmatics are hypersensitive to sulfites.^{146,197} A recent study by Rieschke *et al.* demonstrated increased intubation-induced bronchoconstriction in patients with a long smoking history when sulfite-containing formulations of propofol were utilized.¹⁹⁶

As discussed above, the various allergic problems and bronchospastic reactions which attend the propofol emulsion and preservatives have led to a search for propofol modifications which would be water-soluble. These are now available and will be discussed at the end of the chapter under “Future trends and advancements – on the horizon”.¹⁴⁸

The inclusion of a perishable emulsion carries with it the potential for contamination and postinfusion infection. Periodic outbreaks of bloodstream infections have been reported and appear to be attributable to a breakdown in sterile technique. This underscores the significance of a high level of training of all members of the anesthetic team and diligence in administration of the drug.¹⁰⁷

Other side-effects and complications range from very minor to life-threatening. An interesting side-effect of no clinical importance is the occasional production of green urine following propofol infusions.¹⁹⁸ More severe reactions include the rare case of post-infusion pancreatitis¹⁹⁹ and propofol infusion syndrome.¹⁰⁷ The latter has usually been reported in high infusion rates of 5 mg/kg/h or greater for 48 hours or longer. Consequently, the likelihood of encountering such a complication in an oral and maxillofacial surgery is exceedingly remote.

The impact of propofol on clinical practice

Unquestionably the advent of propofol has been one of the pivotal events in the practice of anesthesia in hospitals, outpatient surgery centers and oral and maxillofacial surgery offices as well. In 2008, Paul F White MD, Chairman of the Department of Anesthesiology at the University of Texas Southwestern Medical Center penned an article in *Anesthesiology* entitled 'Propofol – its role in changing the practice of anesthesia'. When Dr White began his academic career at Stanford University in the early 1980s he was intrigued by the potential of this novel new anesthetic agent. Throughout his career he watched it exert a "revolutionary impact" on the practice of anesthesia.²⁰⁰ In oral and maxillofacial surgery the transition from methohexital to the propofol was somewhat slower than within the practice of anesthesiologists in hospitals and outpatient surgery centers.^{201–203} However, as was discussed in the history section above, the "Brevital crisis" in the early part of the first decade of the 21st century prompted many surgeons to convert to propofol.²⁰⁴ In 2008, Lee *et al.* reported a study on nearly 48 000 patients who underwent ambulatory anesthesia procedures in oral and maxillofacial surgery offices. The study concluded that the lowest risk for adverse events was with propofol as compared to methohexital or benzodiazepines/narcotic approaches.⁵²

Ketamine and dissociative anesthesia

In the late 1950s work began on a new class of anesthetic drugs based on phencyclidine.²⁰⁵ Phencyclidine itself was found to produce unacceptably high levels of dysphoric effects such as hallucinations and deliri-

um. However, because of several of the other desirable characteristics of this type of anesthetic, pharmaceutical research continued with exploration of other agents. In 1970, a phencyclidine congener, ketamine, was released for clinical use,²⁰⁶ and has continued to be the only dissociative anesthetic on the market. The term "dissociative" aptly describes the appearance of the patient under ketamine anesthesia. The patient appears to be in catatonic state, dissociated from the sensory inputs from the environment.³⁴ Corneal, cough, and swallow reflexes are still present and the patient's eyes are still open, but with a distant gaze.¹⁶⁴ Ketamine provides profound analgesia, even at subanesthetic doses.¹⁰⁷ It also causes amnesia, although the latter is not as great as is noted with benzodiazepines. A primary difference between ketamine and other anesthetics is that it is not associated with either hypotension or significant respiratory depression.

Chemical structure

Ketamine is a highly lipophilic arylcyclohexylamine related to phencyclidine which exists in a racemic mixture (Fig. 6b.18) consisting of an S(+) and R(–) enantiomer.²⁰⁷ Only the racemic mixture is available in the US. However, in Europe the S(+) isomer has become clinically available.^{107,208} It is twice as potent as the racemic mixture, it appears to have fewer adverse side-effects, and it is associated with more rapid recovery.

Mechanism of action

Dissociative anesthesia is due to a reduction of activation of thalamocortical structures, but with increased activity in the limbic system²⁰⁹ and hippocampus.²⁰⁵ The major excitatory synaptic receptors in the CNS are mediated by L-glutamate and are termed NMDA (N-methyl-D-aspartate). As discussed above, the receptor ion channel (see Fig. 6b.16) is permeable to calcium as well as sodium and potassium to a lesser extent. The channel requires glycine as an obligatory co-agonist and is inhibited by magnesium (Mg^{2+}) in a voltage-dependent manner. Ketamine binds to the phencyclidine receptor in the NMDA channel and inhibits glutamate activation in a non-competitive fashion. At resting membrane potential the NMDA receptor is inactive because of the

Fig. 6b.18 Structural formulas of the two enantiomers of ketamine. (Reproduced from Kohrs R, Durieux ME. Ketamine: teaching an old drug new tricks. *Anesth Analg* 1998; 87: 1186–93 by permission. Copyright © 1998 Lippincott Williams & Wilkins.)

voltage-dependent block of the channel pore by magnesium ions. Then, as the cell membrane becomes depolarized, the negative field weakens and magnesium ions are released. Consequently, the NMDA channel is both a ligand-gated, as well as voltage-gated, ion channel. By binding at the PCP site, ketamine blocks the open channel and reduces its mean open time.²⁰⁵

Ketamine has effects at several other receptors as well. The analgesic effects of ketamine appear to be due in part to its action on μ and κ opioid receptor sites. It is likely that the psychotomimetic effects are due to action at the κ rather than the μ receptor.²⁰⁵ Muscarinic acetylcholine receptors are inhibited by ketamine which may explain such effects as bronchodilation. This may also explain the increase in bronchial and mucus secretions, and perhaps ketamine's amnesic effect. Interestingly, ketamine tends to affect sodium channels as well, in a manner similar to that of local anesthetics.¹³⁴

The L-type calcium channel is susceptible to the effects of ketamine. Ketamine blocks the calcium channel in a manner somewhat similar to calcium channel blockers such as verapamil. In part this action may help explain the vasodilation, bronchodilation, and negative inotropic effects of ketamine.²⁰⁵

Distribution

Ketamine is highly lipid-soluble, and its effects are noted within seconds of intravenous administration and reach a peak at 1 minute. Its distribution half-life is approximately 10–15 minutes and patients become fully oriented to person, place, and time within approximately 15–30 minutes.³⁴ However, the effects of ketamine may be somewhat prolonged by the co-administration of benzodiazepines, which are usually administered to attenuate the psychotomimetic actions of ketamine.⁶⁴

Biotransformation and excretion

Ketamine undergoes biotransformation in the liver, primarily by N-demethylation.²⁰⁷ The N-demethylated metabolite is active, but has only one sixth of the potency of ketamine.²⁰⁵ Ketamine and its metabolites are hydroxylated and conjugated with water-soluble conjugates that are excreted in the urine. The elimination half-life is approximately 2.5–3 hours.³⁴ Only a small percentage (approximately 4%) of unchanged ketamine is excreted.²⁰⁵ Decreased renal function does not prolong the drug's action.²⁰⁹ It has been found that the elimination in children is approximately twice as rapid as that in adults.

Effects on organ systems

Unlike most other anesthetic agents, ketamine tends to stimulate the cardiovascular system and it is usually associated with increases in blood pressure, heart rate, and cardiac output.²¹⁰ These effects are due to central stimulation of the sympathetic nervous system and inhibition of the reuptake of norepineph-

rine.¹⁰⁶ They are noted with both the S(+) enantiomer and the racemic mixture. The hemodynamic changes are not related to the dose of ketamine, and a follow-up dose of ketamine may actually even diminish the effects of the initial dose.²¹¹ Ketamine appears to inhibit intraneuronal uptake of catecholamines, much like cocaine.³⁴ Obviously, cardiovascular system stimulation is not always desirable, especially in patients with tachycardia or systemic hypertension. The effects can usually be largely overcome with other agents, especially the benzodiazepines. Even in modest doses diazepam and midazolam tend to attenuate the hemodynamic effects of low-dose ketamine.^{209,212}

As compared to most other anesthetic agents, ketamine exhibits an unaltered response to carbon dioxide and has minimal affect on central respiratory drive. Only at very high induction doses is there a transient decrease in minute volume or apnea. Ketamine is a bronchial smooth muscle relaxant, probably as a result of sympathomimetic effects.^{207,213} This activity makes the agent particularly useful in asthmatic patients and it has even been used to treat status asthmaticus in cases which were unresponsive to conventional treatments.^{34,214,219} Ketamine reduces bronchoconstriction via antagonistic effects of the vagus nerve and attenuates opioid-induced hyperventilation.²¹⁵ On the negative side, ketamine tends to increase salivation which can be a contributing factor in the development of laryngospasms.³⁴ However, the hypersalivation affect can be attenuated with anticholinergics such as glycopyrrolate or atropine.^{64,106,164}

Ketamine crosses the blood-brain barrier rapidly with an onset of action within 30 seconds and maximal effect within 1 minute. It is rapidly redistributed from the brain and blood to other tissue. When administered alone, it can produce emergence reactions such as vivid dreaming, extracorporeal expressions, and illusions.²⁰⁶ However, when ketamine is given at low doses, these psychotomimetic effects can be largely overridden by benzodiazepines,^{134,209} especially midazolam 0.025–0.050 mg/kg.¹⁶⁴ Emergence reactions are rarely noted in pediatric patients and are less commonly seen in males as compared to females. In addition, low doses at slower rates tend to minimize them³⁴ and they are often not remembered by the patient.²¹⁶

Ketamine increases cerebral oxygen consumption, cerebral blood flow and intracranial pressure. Interestingly, under controlled ventilation ketamine does not increase intracranial pressure. Yet another CNS effect of ketamine is its neuroprotective action¹⁰⁷ which has been demonstrated in numerous *in vitro* studies. However, this will need further clinical studies to assess whether there are any true benefits of ketamine in the treatment of patients with neuronal damage.

Complications and side-effects

Overall, ketamine is considered to be a relatively safe anesthetic with a wide therapeutic range. Even in

cases in which patients have been given ten times the normal dose of ketamine, there has been uneventful recovery. As discussed above, some of its less desirable effects such as hypersalivation and cardiovascular stimulation can be easily minimized with antisialogogues¹⁰⁷ and benzodiazepines respectively. In addition, when ketamine is used at relatively low doses, its psychotomimetic tendencies can also be attenuated with benzodiazepines, especially midazolam.¹⁰⁶

When there are significant advanced comorbidities, some of the above problems can constitute contraindications. These include severe cardiovascular disease such as angina,²⁰⁹ severe hypertension with multiple antihypertensive agents, glaucoma which is poorly controlled,¹³⁴ severe psychotic illnesses with suboptimal control with psychiatric medications³⁴ and pregnancy, especially in the first trimester.

Effect on clinical practice

In 1998 an article entitled ‘Ketamine: teaching an old drug new tricks’ appeared in *Anesthesia and Analgesia*, the journal of the International Anesthesia Research Society.¹³⁴ It followed the course of ketamine from the initial enthusiasm for the drug, its fall into disfavor, and finally the resurgence of interest which occurred at the close of the 20th century. The drug’s beneficial effects far outweigh its detrimental effects, and the latter can be largely overcome when ketamine is used in combination with other agents as part of a balanced technique. During the latter years of the 20th century and the first decade of the 21st century, numerous reports began to appear demonstrating the successful use of low-dose ketamine as a part of a balanced anesthetic, especially in combination with propofol. Consequently, it does appear that, indeed, it is possible to “teach an old drug new tricks”.

The complementary effects of propofol and ketamine

As is apparent from the description of the primary agents propofol and ketamine discussed above, these agents tend to have many complementary effects. Some of the principle characteristics are compared and contrasted in Table 6b.2.

The complementary effects of the two agents have not gone unnoticed. These complementary effects can be capitalized upon in the development of a balanced anesthetic approach. Anesthesiologists and oral and maxillofacial surgeons throughout the US and abroad have used the agents in various combinations in a number of different clinical settings. These include: pediatric oncology,²¹⁷ pediatric burn dressing changes,⁴³ anorectal surgery,⁴² cosmetic surgery,^{41,218,219} emergency department,^{220,221} traumatic brain surgery,²²² as well as oral and maxillofacial surgery.⁴⁰ Although the vast majority of these reports suggest a definite benefit to the combination of propofol and ketamine, some have not.^{223–225} As yet there are no

large studies under controlled conditions which provide a definitive comparison between propofol anesthesia and anesthesia with the combination of propofol with ketamine. Albeit truly definitive studies are not yet available, the author’s experience with well over 8000 oral and maxillofacial surgery cases has been decidedly positive, as will be discussed below.

The studies which have found the combination to be beneficial allude to the diminution of marked fluctuations in cardiovascular and respiratory parameters, better intraoperative and postoperative analgesia and rapid recovery with little in the way of dysphoria. Other benefits include diminished pain on propofol injection,²²⁶ earlier recovery of cognition,²²⁷ and improvement of postoperative depressive state in depressed patients.²²⁸ Virtually all of the studies point to a lessened requirement of postoperative opioid analgesics.^{229,230}

Ancillary agents

Historically it was always hoped that pharmacologic research would unveil a monoanesthetic agent that would have all of the characteristics desirable in an anesthetic agent.^{64,206} The agent could literally be “turned on” and “turned off” and would exhibit virtually no untoward effects. Then, when an agent failed to meet expectations (as in the case of ketamine), interest would wane and the search would continue for yet another “perfect agent”. Ultimately the agent which has come closest to expectations has been propofol. However, it too has shortcomings and the use of other agents along with propofol is necessary to obtain the multiple characteristics which are today considered essential in an anesthetic. Out of the wide range of agents that have been used over the years, this chapter will now discuss some of those which currently enjoy the widest popularity in hospital operating rooms, outpatient surgery centers, and oral and maxillofacial offices.

Anxiolytics

Preoperative anxiety has been shown to increase the demand for principal anesthetic agents²³¹ and can be responsible for patient dissatisfaction with anesthesia.²³² Consequently, it behoves the anesthetist to deal directly with patient anxiety rather than attempt to overcome it with large doses of primary anesthetic agents. The agents which have been found to be of greatest benefit in dealing with patient anxiety include the benzodiazepines and nitrous oxide.

Midazolam

Diazepam, introduced in the 1960s, initially enjoyed wide popularity as a component of methohexital-based anesthesia in oral and maxillofacial surgery.³⁷ However, its protracted biotransformation and elimination and vein irritation prompted a search for a water-soluble agent with shorter action.^{233,234} This investigation led to the development of midazolam, which began to overtake diazepam as the preferred anxiolytic by the turn of the 21st century. Midazolam is water-soluble and rarely leads to thrombophlebitis.²³⁴ It provides greater sedation and more profound anterograde amnesia, yet is shorter-acting than diazepam.²³⁵ Like other benzodiazepines, it possesses anticonvulsant and muscle relaxant properties. It has relatively little cardiovascular effect except for diminution of sympathetically induced hypertension.²³⁵ In large, rapidly introduced boluses it can induce respiratory depression, and the patient's respiratory status must be diligently monitored. When the agent was initially introduced, its markedly greater potency^{34,236} than diazepam (especially in conjunction with fentanyl) went unrecognized by some practitioners, and respiratory depression,^{149,237} and even deaths, were recorded.²³⁸ However, it became apparent that the problem was inadequate respiratory monitoring rather than a fault of the drug itself. Today midazolam is the most widely used benzodiazepine in anesthesia practice.³⁴ It is used intravenously as a preinduction agent, as a component of moderate ("conscious") sedation and as oral premedication in pediatric patients.²³⁴

Other benzodiazepines

Several different benzodiazepines have been used as oral premedication in oral and maxillofacial surgery. These include diazepam, lorazepam, and triazolam. However, trials comparing different benzodiazepines have failed to demonstrate consistent differences in efficacy among the different agents.²³⁹ Of the various agents available, the one which appears to have the most desirable pharmacokinetic and pharmacodynamic properties is triazolam.^{240,241} It reaches peak blood level at approximately 1 hour and has an elimination half-life of only 2–3 hours. This is in large part due to the absence of active metabolites. Triazolam is usually used in a dose of 0.25–0.5 mg for adult patients, except the elderly. The latter are quite sensi-

tive to benzodiazepines and a dose of 0.125 mg or less is appropriate for patients of advanced age.²⁴² Although its pharmacokinetic and pharmacodynamic profile makes triazolam an excellent agent for anesthesia premedication, in the late 1980s and early 1990s the drug's acceptance suffered from a number of sensational media reports. The latter suggested that triazolam might be associated with extreme excitation and even violence.²⁴³ Subsequent scientific investigation disclosed that triazolam shared the same exceedingly safe drug profile of the other benzodiazepines and that the immediate concern was unjustified.^{244,245} Today the medication is used widely for both anesthesia premedication and oral sedation in dentistry.²⁴⁶

Although, as stated above, benzodiazepines as a group are relatively safe medications, respiratory depression can be significant, and even life threatening. Consequently, efforts were directed at developing a specific benzodiazepine antagonist. These efforts resulted in the development of flumazenil in 1979.³⁴ However, it did not become available clinically in the US until the early 1990s.²⁴⁷ As a typical competitive antagonist, it has minimal intrinsic effects of its own and replaces benzodiazepine agonists at the receptor site. However, its short duration of action (plasma half-life of approximately 1 hour) can create a false sense of security. The reversal may be far more short-lived than the respiratory depression associated with the original agonist. Consequently, the patient should be observed following administration of flumazenil to assure that re sedation does not take place.²⁴⁸ The initial reversal dose is 0.1–0.2 mg. Repeat doses can be given up to a total dose of 3 mg.³⁴

Nitrous oxide

Nitrous oxide has been the "workhorse" inhalation agent in anesthesia for over 150 years.²⁴⁹ It tends to relieve anxiety, reduces the incidence of intraoperative awareness,²⁵⁰ and provides a synergistic effect with sedative and hypnotic agents, thereby reducing the dose of the primary anesthetic agent required. It also has analgesic effects which appear to be related to activation of opioid receptors²⁵¹ in the periaqueductal gray matter and noradrenergic neurons in the locus ceruleus.²⁵² Nonetheless, within recent years there have been some concerns regarding possible nitrous oxide toxicity.²⁵³ It appears to affect methionine synthase function which could potentially lead to genetic and protein aberrations.²⁵¹ An extensive review of potential adverse effects of nitrous oxide was presented in an article entitled 'Biologic effects of nitrous oxide' in *Anesthesiology* in 2008.²⁵⁴ It concluded that it would be prudent to avoid nitrous oxide in certain vulnerable populations, but abandonment of the agent is not indicated based on current scientific studies. Similar conclusions were drawn by Ian Smith in his review in 2006²⁵⁵ and by Philip Hopkins in another review in 2005.²⁵⁰ Absolute contraindications²⁵⁴ would include patients of known deficiency

of the enzyme or substrate in the methionine synthase pathway, patients with raised intracranial pressure, and patients with gas-filled space such as those with emphysema, pneumothorax or those undergoing middle ear surgery. Relative contraindications would include patients with pulmonary hypertension, patients in their first trimester of pregnancy, and patients who are at a high risk of postoperative nausea and vomiting.

In addition to the toxic effects of nitrous oxide which can be experienced by patients, there is also a risk to office personnel. To minimize these risks, scavenging systems have been in place in dental offices for over half a century. Scavenging is intended to limit the concentration of nitrous oxide in the operator to meet standards established by governmental agencies. The safe limit established by the National Institute for Occupational Safety and Health (NIOSH) is 50 ppm (parts per million) while that for the American Conference of Governmental Industrial Hygienists (ACGIH) is 25 ppm.²⁵⁶ A study reported in the *Journal of American Dental Association* in February 2009²⁵⁷ compares the levels achievable for a conventional scavenging mask and a newly designed mask with enhanced features (the Safe Sedate dental mask, Airgas, Rednor, PA), which is shown in Fig. 6b.19. The new mask delivers the anesthetic gas directly into each naris via an adjustable cannula which passes through the mask. The wasted anesthetic gas is scavenged from the chamber which houses the mask via a single hose that is attached to the vacuum system. The balloon of the mask is designed to provide excellent adaptation, and the mask is held in place with straps which go around the patient's head.

The comparison used infrared thermography, digital videography, and real time nitrous oxide air concentration levels with infrared spectrophotometry. It was found that the advanced features of the new mask provided better reduction of nitrous oxide, especially in conjunction with key work practices which included proper mask sizing and fitting, activating the exhaust before administration of nitrous oxide, and discouraging the patient from talking and mouth breathing. Statistically significant results were obtained when these practices accompanied use of the new mask. Fig. 6b.20 demonstrates the difference in mask leakage disclosed by infrared thermography.

Another key issue in limiting staff exposure to nitrous oxide is design of the office ventilation system. Since nitrous oxide is heavier than nitrogen and the other components of air, there is stratification with nitrous oxide settling in the lower part of the room. Many offices have exhaust vents in the ceiling which tend to exhaust predominantly air in the top of the room, leaving much of the nitrous oxide around the operative team. Evacuation of the residual nitrous oxide which has been inadequately scavenged requires placement of exhaust vents on the floor or

lower portion of room walls rather than the ceiling.²⁵⁸

Opioid analgesics

Opioid analgesics were an essential component of most balanced anesthetic approaches for the better part of the last century. In modern practice the older agents such as morphine sulfate and meperidine have been replaced by the newer agents, fentanyl and remifentanyl of the anilidopiperidine series. Although

fentanyl is currently the most frequently used of these drugs,¹⁰⁴ remifentanyl is gaining popularity.

Fentanyl

Fentanyl is the original anilidopiperadine opioid and has gained wide popularity in anesthesia. It is a μ receptor agonist which is 100 times as potent as morphine and has a rapid onset of less than 1 minute.³⁶ Its short duration of 30–60 minutes²⁵⁹ makes it an ideal narcotic for outpatient surgery in general and oral and maxillofacial surgical anesthetics in particular.²⁶⁰ There is less histamine release than with meperidine, which makes the agent more appropriate for asthmatic patients than its predecessor.²⁶¹ There appears to be a similar incidence of nausea and vomiting as was noted with most of the other opioid agents used previously.³⁶ The cardiovascular system remains relatively stable, but the patient may develop modest bradycardia.¹⁰² Chest wall rigidity has been reported, but appears to be related to relatively large doses¹⁰⁶ and has been infrequently encountered in oral and maxillofacial surgery practice.

Remifentanyl

The newest drug in the anilidopiperadine family is remifentanyl,²⁶² a μ agonist introduced in 1996,^{221,263} which differs from the previous opioid agents in that it is metabolized by esterases throughout the body (Fig. 6b.21).²⁶⁴ Consequently, there is very rapid dissipation of the clinical effects of the drug once an infusion has been discontinued. It also has a pK_a that is less than physiologic pH, which allows circulation of the drug in its non-ionized moiety. This in turn enables rapid penetration of the blood–brain barrier.^{102,265} Although it has an analgesic potency similar to that of fentanyl,²⁶⁶ the pharmacokinetic properties of remifentanyl lead to an onset of action of 1 minute^{36,267–269} and duration of action of only 5–10 minutes following discontinuation of the infusion.²⁵⁹ Because its metabolism is based on non-specific esterases, remifentanyl's pharmacokinetics profile is independent of end-organ failure.^{261,270} Since the elderly have a smaller volume of distribution and slower clearance,²⁶⁵ patients over the age of 65 should have

the dosage of remifentanyl decreased by at least 50%.²⁶⁸ Dosing of obese patients should be based on lean body mass rather than total body weight.^{262,271,272} Studies in the use of remifentanyl in oral and maxillofacial surgery point to rapid recovery, decreased propofol requirements,⁴⁵ and more stable cardiovascular parameters.⁴⁴ Remifentanyl can be administered as a separate infusion, with incremental boluses or as a combined infusion with propofol.

Anticholinergics

Anticholinergic agents are frequently indicated for the control of salivary and bronchial secretions.²⁷³ In particular, they can be of benefit in the management of the hypersalivation which accompanies administration of ketamine. Pharmacologic control of secretions helps to prevent laryngospasms, and anticholinergic medications have been the primary agents used. The older belladonna alkaloids, scopolamine and atropine, are tertiary amines and cross the blood–brain barrier where they can have untoward psychological affects.²⁷⁴ In addition, the tachycardia produced by the vagolytic effect of these agents may be undesirable in older, medically compromised patients. Consequently, atropine and scopolamine have been largely replaced in anesthesia by a potent quaternary anticholinergic, glycopyrrolate.²⁷⁵ Although the latter may cause mild tachycardia, it is far less prominent and of shorter duration. As a quaternary ammonium agent, it does not cross the blood–brain barrier and carries with it no untoward mood affects or psychotomimetic reactions.²⁷⁶ As an antisialogogue it is far more potent and the effect may last two to five times longer (up to 8 hours) than that of atropine.²⁷⁷

Antiemetics

In surveys of patient acceptance, lack of postoperative nausea and vomiting is considered a highly desirable trait of anesthetics.^{66,278,279} Postoperative nausea and vomiting (PONV) is the most frequent side-effect after anesthesia. Consequently, over the years many antiemetic medications have been used to help control or eliminate emesis and nausea following anesthesia. Historically the more effective agents tended to be dopamine (D_2) receptor antagonists such as the phenothiazines and metoclopramide. However, in the 1990s a new category of exceedingly effective antiemetic medications was developed, the 5-HT₃ receptor antagonists.^{56,280} The prototypic drug in this class is ondansetron which now enjoys wide use in the treatment of chemotherapy-induced emesis as well as anesthesia-associated nausea and emesis.²⁸¹ Combination therapy is more effective than monotherapy.^{280,282–286} An especially effective combination is a 5-HT₃ receptor antagonist accompanied by a potent corticosteroid such as dexamethasone.^{279,281,286–288}

Inhalation agents – sevoflurane

Historically, oral and maxillofacial surgeons have tended to prefer the total intravenous anesthetic approach as opposed to inhalation anesthesia. However, with the introduction of sevoflurane in the 1990s,²⁸⁹ an agent became available which possessed far more desirable characteristics than its predecessors.⁶³ Sevoflurane has a number of appealing attributes which have encouraged greater use of inhalation anesthesia in some oral and maxillofacial surgery practices.³⁷ Sevoflurane anesthesia is characterized by rapid onset and emergence,^{290,291} a pleasant smell,²⁹² lack of airway irritation,²⁸⁹ and lack of myocardial irritability.^{63,291} Nonetheless, like all inhalation anesthetics, it has the significant liability of being a potential triggering agent for malignant hyperthermia.²⁹⁰ Consequently, offices using the agent must be prepared with dantrolene and training in the treatment of malignant hyperthermia.⁴⁹

Balanced anesthetic approaches currently used in oral and maxillofacial surgery practices

Sedation and anesthesia in oral and maxillofacial surgery today cover a wide range of drugs and techniques. They can produce a depth of sedation which ranges from minimal sedation to general anesthesia. In recognition of this continuum, the ASA published its *Practice Guidelines for Sedation and Analgesia by Non-anesthesiologists* in 2002.^{293,294} In that article it was stated, "Because it is not always possible to predict how a specific patient will respond to sedative and analgesic medications, practitioners intending to produce a given level of sedation should be able to rescue patients whose level of sedation becomes deeper than initially intended." It is important that the oral and maxillofacial surgeon remains constantly aware of this continuum in choos-

ing and monitoring the anesthetic chosen for a given patient. In a healthy teenager or young adult, a patient may pass through each the four levels of the continuum during his time in the office. The four levels are as follows:

1. Minimal sedation (anxiolysis) – there is normal response to verbal stimulation with the airway, ventilation, and cardiovascular function unaffected.
2. Moderate sedation ("conscious sedation") – purposeful response to verbal or tactile stimulation with no compromise of the airway and ventilation and cardiovascular function usually maintained.
3. Deep sedation/analgesia – purposeful response after repeated or painful stimulation with possible need for maintenance of airway and ventilation and cardiovascular function usually maintained.
4. General anesthesia – patient unarousable, even with painful stimulation, airway intervention required with possible support of ventilation and possible impairment of cardiovascular function.

Fig. 6b.22 graphically illustrates the levels of sedation through which a typical patient passes during routine dentoalveolar surgery such as third molar removal. The agents which provide the appropriate level of sedation for the various stages of treatment are as follows:

1. Preoperative anxiety – oral premedication with an anxiolytic can induce a state of minimal sedation and anxiolysis which reduces the demand for the primary anesthetic agent.
2. Nitrous oxide can be administered prior to the venipuncture to reduce anxiety regarding the needle stick as well as preoxygenate the patient.
3. Preinduction agents including a benzodiazepine and narcotic establish a state of moderate sedation

Fig. 6b.22 The levels of sedation during intravenous anesthetic. Appropriate agents transport the patient through several levels of sedation to a plane of surgical anesthesia during which the procedure is performed. These include: A. Reduction of preoperative anxiety with oral premedication. B. Anxiolysis and preoxygenation with N_2O/O_2 . C. Preinduction medication with preinduction agents such as a benzodiazepine and narcotic. D. Induction with propofol (and possibly ketamine). E. Maintenance with a propofol infusion. F. Discontinuation of infusion with emergence.

which provides amnesia and analgesia and “balancing” of the anesthetic.

4. Induction with a potent hypnotic such as propofol and possible dissociative anesthesia with ketamine. Just after induction while the patient is in a state of deep sedation/general anesthesia, local anesthesia is administered, which subsequently reduces the anesthetic requirement.
5. The patient is maintained on a continuous infusion of propofol to maintain a level of consciousness bordering deep sedation and general anesthesia.

Method of delivery

Historically the primary barbiturate anesthetics thiopental and methohexital were delivered in small incremental boluses (the “bump” technique). As most oral and maxillofacial surgeons made the transition from methohexital to propofol, they tended to continue with the same method¹⁴⁰ but used smaller boluses at more frequent intervals.²⁹⁵ Some anesthesiologists have found the technique to be satisfactory, but many others have desired to capitalize on the “smoothness” of a constant infusion via infusion pump.^{163,296,297} Fortunately, simple, syringe-based infusion pumps have been developed which enable ease of administration of the anesthetic and elimination of the need to constantly administer boluses.²⁹⁸ Surgeons who have made the transition to an infusion pump find that there is another advantage beyond the greater smoothness of the anesthetic. There is less likelihood of patient awareness during the procedure when there is no interruption of the infusion, as often takes place during manual bolus administration.²⁹⁹ A typical pump which has been a “workhorse” delivery system in many operating rooms and outpatient surgery centers is pictured in Fig. 6b.23. Newer, totally digital pumps are appearing in the marketplace. However, a number of anesthesiologists have found them to have “too many bells and whistles” and, in some cases, to be less reliable.³⁰⁰ Consequently, many prefer to continue to use the partial analog device described here. Details on the use of the pump will be provided below in the discussion of the author’s technique for total intravenous anesthesia.

Total intravenous anesthesia (TIVA)

In the US most oral and maxillofacial surgeons currently use a total intravenous anesthetic approach based on propofol, and in some cases, propofol with ketamine. The choice of ancillary agents and dosages is highly variable from surgeon to surgeon.¹⁴⁰ Attempting to address this wide range of variables is beyond the scope of this chapter; the author’s technique will be described as an example. The author co-directs the outpatient anesthesia curriculum within the Oral and Maxillofacial Surgery Department at the University of California at San Francisco. The technique has been used for over 8000 patients in the

author’s private practice, and it has been taught to the oral and maxillofacial surgery residents who now also use it in the various outpatient surgery clinics in which they perform dentoalveolar and implant surgery.

The technique is based on a combination approach with propofol and ketamine, with the propofol administered via an infusion pump. The technique was developed with contributions from the literature as well as from anesthesiology colleagues of the author. As such, it illustrates several important points that have been made in the anesthesia literature over the last several years:

1. The components of balanced intravenous anesthesia do not always act in a synergistic fashion. For example, the addition of ketamine to propofol anesthesia adds dissociation but little in the way of enhancement of hypnosis.^{301,302}
2. Drug interactions with intravenous anesthetics are not always detrimental. For instance, the hypotensive effects of propofol are frequently largely overcome by the hypertensive affects of ketamine when it is added to the mix.³⁰³
3. The “short-acting” agents from merely a few years ago are now “long-acting” in comparison to intravenous propofol and ketamine and remifentanyl. For instance, midazolam and fentanyl were shorter acting than their predecessor benzodiazepines and narcotics. However, they are considerably longer acting than propofol and ketamine. Consequently, the smallest effective dose possible of these agents should be used to promote more rapid recovery. In most cases, 2mg of midazolam and 50µg of fentanyl provide the desired characteristics to the anesthetic without significantly prolonging recovery.
4. A propofol-based anesthetic has attributes which distinguish it from virtually all other forms of intravenous or inhalation agents. For instance, the inherent antiemetic effects and postoperative feeling of well-being which accompany propofol anesthesia lead to a high level of patient acceptance.^{144,200}

Fig. 6b.23 The Baxter Infus O.R. partial-analog anesthesia infusion pump.

5. Propofol can be used in either its sedative or anesthetic mode, and is hence very flexible for use in different patient populations. Often sedation is the more appropriate anesthetic approach for elderly and/or medically compromised patients. Sedation is also a more appropriate means of managing long implant cases. In both these settings, propofol can be used very effectively for sedation as opposed to deep sedation or surgical anesthesia.³⁴

The author's office-based anesthesia technique

The author's technique embraces the various principles outlined above and is described below.

Oral and anesthetic premedication

Sedation and anxiolysis is provided by triazolam 0.25–0.5mg PO. Dosages are reduced commensurately for elderly patients and given on a weight basis to pediatric patients. For children who have difficulty swallowing tablets, the medications are crushed into a powder and given with a concentrated, pulpless fruit punch. Since ketamine is a component of most of the intravenous anesthetics, glycopyrrolate is given as an antisialagogue with a usual dose of 2mg PO with scaled doses for children. For middle-aged and older males with potential benign prostatic hypertrophy, no glycopyrrolate is dispensed. To counteract gastric hyperacidity the H₂ antagonist ranitidine is given in two doses. The first dose of 150mg is given to be taken at bedtime on the night before the procedure and the second with the other anesthetic premedications 1 hour prior to the procedure.

Preparation for venipuncture and the preinduction agents

Prior to establishment of intravenous access, nitrous oxide and oxygen 40–60% are administered via face-mask. For adults, the venipuncture site is prepared with a spray of ethyl chloride. For children, EMLA cream is placed 1–1½ hours prior to venipuncture. These agents are discussed in greater detail in the perioperative management section below.

The intravenous route is established with a catheter-over-needle device and a continuous infusion of normal saline administered throughout the procedure. The first agent introduced is midazolam 0.02–0.03mg/kg of lean body mass. This provides satisfactory amnesia, relaxation, and anxiolysis without prolonging recovery. The preinduction narcotic consists of either fentanyl or remifentanyl. In the case of fentanyl, the usual initial dose for a 70kg patient is 50µg and it is rarely repeated. When remifentanyl is used, it is added to the propofol infusion (50µg per 20ml propofol) as discussed below. If it appears that there are still excessive secretions in the face of the oral glycopyrrolate, an additional 0.2–0.25mg of glycopyrrolate is administered.

Induction and maintenance

The dosages for induction and maintenance of propofol and ketamine are based on distribution groups as outlined in Box 6b.1. Note that the induction dose of ketamine is half of the induction dose of propofol as determined by the table. For most cases the low-dose ketamine bolus given at the beginning of the procedure is adequate for completion of the surgery. In patients who are resistant to medication, incremental ketamine doses of 5–10mg are given every 10–15 minutes during the procedure. In children the incremental doses are given routinely, usually in increments of 2.5–5mg. For patients over the age of 60, no ketamine is administered.

In most cases remifentanyl is used in conjunction with propofol. It is reconstituted and diluted 1:20, 1ml of a 50µg/ml remifentanyl solution is added to each 20ml multiple-dose vial of propofol. In keeping with other series reported in the oral and maxillofacial surgery literature, the author has found that use of remifentanyl as a component of balanced anesthesia has shortened recovery and allowed less fluctuation in cardiovascular parameters.^{44,45}

Intravenous sedation

For certain patient groups intravenous sedation is preferable to total intravenous anesthesia. Examples would include elderly and/or medically compromised individuals and those undergoing implant surgery. Traditionally cases such as these have been managed with a combination of a benzodiazepine (usually midazolam) and a narcotic (usually fentanyl). However, a number of anesthesiologists, as well as the author, have found that use of propofol in its sedation mode will often provide a more desirable anesthetic course. In this setting a small dose of midazolam and fentanyl is given at the beginning of the procedure and followed with a low-dose propofol infusion. The latter provides excellent sedation for the procedure, but more rapid recovery than that which is usually seen with multiple incremental doses of benzodiazepine and narcotic.

Local anesthesia

A consistent cornerstone in any balanced anesthetic is satisfactory analgesia. In oral and maxillofacial surgery a large component of an anesthetic's analgesia is provided by local anesthesia, as opposed to heavy doses of intravenous agents.^{304–306} Thus it behoves the operator-anesthetist to provide the best possible local anesthesia to obviate the need for large doses of narcotic and/or ketamine to obtain adequate relief from pain. A thorough knowledge of the anatomy of local anesthesia and local anesthetic technique are essential in the delivery of satisfactory outpatient anesthesia. In addition, judicious use of the agents themselves can provide a more comfortable anesthetic course for the patient.

Box 6b.1 The author's dosing guidelines for administration of propofol, ketamine, and remifentanyl for office-based anesthesia. The propofol and remifentanyl are delivered via the Baxter Infus O.R. Anesthesia Infusion Pump. A separate syringe is used to administer the induction bolus of ketamine. Subsequent incremental boluses of ketamine are used routinely for pediatric patients, but only on a prn basis for teens and adults. At the top of each column is a graphic depiction of the pump settings used for the administration of propofol for each age group of patients. Beneath the graphic depiction of the pump are the guidelines for the dosing of ketamine which is used in conjunction with propofol. When remifentanyl is administered in combination with propofol, 1 ml of a 50 µg/ml solution is added to each 20 ml vial of propofol.

Anatomic considerations

The greatest incidence of failure in providing adequate local anesthesia is in what is traditionally considered the distribution of the mandibular division of the trigeminal nerve (V_3).³⁰⁷ This may be due to poor technique, lack of appreciation of cross-innervation, and anatomic variability. Both the traditional "cross arch" mandibular block procedure technique with a straight needle^{308,309} or the Gow-Gates³¹⁰ approach are technique-sensitive.

Another approach used by the author, as well as a number of other surgeons, is based on an appreciation of the anatomy of the medial aspect of the mandibular ramus obtained through experience performing the sagittal ramal split osteotomy. Surgeons experienced in the technique are aware of the high degree of variability in the prominence of the medial buttress of the coronoid process which begins at the base of the process and descends down the medial aspect of the anterior portion of the mandibular ramus. The prominence of the buttress and marked flaring of the ramus will at times make visualization of the neurovascular bundle rather difficult as it enters the mandibular canal inferior to the lingula.

This same buttress often presents an impediment to the delivery of local anesthetic to the appropriate location using the traditional straight-needle approach. The author's technique calls for incorporating a gentle curvature in the needle (Fig. 6b.24) to enable it to pass over and posterior to the buttress directly to the mandibular groove (Fig. 6b.25). Traditionally students have been admonished to "never bend a needle" because of needle fractures that have occurred when sharp, angular bends have been incorporated into local anesthetic needles, especially at the hub.³¹¹ However, the gentle curvature as described and illustrated in Fig. 6b.24 does not substantially weaken the needle and allows deposition of the local anesthetic in the appropriate location. As a matter of fact, with a slight curvature, the needle can be used as a "sound" to verify that the tip is indeed in the mandibular groove.

A frequent cause of inadequate local anesthesia in the mandible is the failure of the operator to appreciate the complexity of the innervation of the mandible and perimandibular soft tissues. In recent years the problem has become more pronounced because of new procedures which are performed at the periphery of the areas in which traditional mandibular out-

Fig. 6b.24 Incorporation of a gentle curvature in a 25 gauge 38 mm (1½ inch) needle in preparation for a mandibular block.

Fig. 6b.25 The slight curvature allows passage of the needle around the medial coronoid buttress to the mandibular groove.

patient procedures were performed. In particular, monocortical ramus and symphyseal grafts used in implant surgery require dissection in areas not adequately anesthetized by conventional local anesthetic approaches in the mandible.

Although the third division of the trigeminal nerve provides innervation to much of the mandible and the perimandibular soft tissues, a significant contribution is provided by the greater auricular and transverse cervical branches of the cervical plexus (see Fig 6b.26).³¹² Consequently, local anesthetic must be administered along the lateral aspect of the mandibular ramus and posterior mandibular body to take into account the innervation by greater auricular nerve. Anteriorly the branches of the transverse cervical nerve provide innervation along the inferior border of the mandible and beneath it. Thus local anesthetic must be given in these areas in order to achieve adequate anesthesia.

Another failure of mandibular anesthesia can be attributed to the anastomoses which exist between branches of the facial nerve (CN VII) and the trigeminal nerve and cervical plexus branches previously described (Fig. 6b.27).³¹³ The periosteum enveloping the mandible contains nociceptors from all three sources and wide infiltration in the areas of monocortical graft harvest is usually required.^{314–316}

Sensory branches from the mylohyoid nerve can also provide innervation to the lingual aspect of the

Fig. 6b.26 Innervation of the face and submandibular region. An important portion of the lower portion of the face along the lower and posterior borders of the mandible receives its innervation from the greater auricular and transverse cervical branches of the cervical plexus. (Reproduced from *Miller's Anesthesia* (Miller RD, ed.), 6th edn. New York: Elsevier/Churchill Livingstone, 2005; 1709, Fig. 1, by permission. Copyright © 2005 Elsevier.)

mandible in the face of an otherwise profound mandibular block. This may be in part due to individual patient variability in the level at which the nerve takes its origin from the third division of the trigeminal nerve.^{317,318} Once again, wide infiltration in the area of the distribution of the mylohyoid nerve on the medial aspect of the mandible is required to overcome this inadequacy in the delivery of profound mandibular anesthesia.

In the maxilla, the posterior portion of the hard palate receives innervation from the lesser palatine nerves as well as the greater palatine nerve (Fig. 6b.28).³¹⁹ Inadequate anesthesia in this area can be troublesome unless this anatomic relationship is appreciated. In the removal of maxillary third molar teeth, infiltrations of the palatal aspect of the posterior alveolus and tuberosity region are often necessary to adequately anesthetize the area for third molar removal.

There is extensive collateral innervation of the hard palate involving the nasopalatine nerves and the greater palatine nerves bilaterally (Fig. 6b.28).³¹⁹ Adequate anesthesia for surgery in the anterior palate will often require a greater palatine nerve block (or bilateral blocks) in addition to a nasopalatine nerve block.

The operator-anesthetist must be cognizant of these complexities of local anesthetic administration. When the patient begins to respond to surgical stimulation, reassessment of the adequacy of local anesthesia should be addressed, as opposed to merely administering large doses of intravenous anesthetic agents.

Local anesthetic agents

In the latter decades of the 20th century and first decade of the 21st century, new amide local anesthetics prilocaine, bupivacaine, and articaine became

Fig. 6b.27 Anastomoses between branches of the cervical plexus and CN VII. These sensory fibers contribute to the sensory innervation of the lower portion of the face and the medial aspect of the mandible. Fig. 6b.28 Sensory innervation of the palate. Reproduced with permission from *Anatomy for Surgeons: The Head and Neck* (Hollinshead WH, ed.), 2nd edn. New York: Hoeber Medical Division, 1968. Copyright © Lippincott Williams & Wilkins.)

available. These agents have properties which enable them to address needs not met by previous local anesthetics. Prilocaine, introduced in the mid-1960s, is potent and is available in a 4% concentration, which often enables the administration of adequate local anesthetic without epinephrine. This can be of benefit in patients who are sensitive to epinephrine or have severe cardiovascular disease which precludes its use. However, prilocaine can induce methemoglobinemia in higher doses,³²⁰ and it appears to be associated with more frequent reports of paresthesia than other local anesthetics.³²¹

In 1963 another new amide local anesthetic, bupivacaine, became available in the US.²⁴ It is considerably longer acting than traditional amide local anesthetics such as lidocaine and mepivacaine. Surgical patients who have received bupivacaine

often do not require postoperative pain medication until several hours after their anesthetics. By the time narcotic pain medication is necessary, the dizziness and sedation associated with the anesthetic have dissipated considerably, and it has been possible for the patient to take in oral fluids or a liquid diet. Thus, when narcotic pain medication does become necessary, it is less likely to cause nausea. Since some patients find the protracted period of anesthesia and hypesthesia unpleasant, it is best to advise the patient and/or his escort of the rationale for use of the long-acting anesthetic.

Within the last decade a final amide local anesthetic, articaine, has become available in the US.³²² It initially appeared that the agent might have greater potency than other anesthetics such as lidocaine, and it became quite popular. However, subsequent double-blind studies suggest that the efficacy of the agent is comparable to the more traditional lidocaine.³²³ The apparent potency of the agent appears to be in part due to the 4% solution in which it is formulated. In the 1990s reports from Haas in Canada suggested that articaine might be associated with a greater incidence of nerve toxicity leading to postoperative paresthesia.³²⁴ However, subsequent reports by Pogrel³²¹ in California in the US did not confirm any greater incidence of paresthesia with articaine as opposed to lidocaine.

Perioperative management

Preoperative preparation

Today the modern oral and maxillofacial surgery office has the appearance of, and functions as, a small

outpatient surgery center. As a consequence, perioperative management of patients treated in these offices is increasingly similar to that which a patient would encounter in an outpatient surgery center. By the end of the 20th century, the majority of surgical procedures were being performed in an outpatient setting.³⁵ Considerable data have been generated within the anesthesia literature regarding the enhancement of the anesthetic experience which accompanies careful attention to perioperative management. The astute oral and maxillofacial surgeon stands to learn much from these studies of perioperative management in the anesthesia literature. Some of those aspects which have particular application in an oral and maxillofacial surgery practice will be examined here.

Management of preoperative anxiety

There is a large body of data within the anesthesia literature examining the profound effect of high levels of preoperative anxiety on anesthetic outcomes.²³¹ If this anxiety is not appropriately managed, intraoperative anesthetic requirements increase, patient's satisfaction with the anesthetic diminishes, and in children there is an increase in emergence delirium and postoperative maladaptive behavior.³²⁵ Having a preoperative consultation appointment to discuss both surgical and anesthetic issues tends to diminish this anxiety.³²⁶ At the appointment it can also be determined whether one or more forms of preoperative medication would be appropriate for the given patient. In both adults and children benzodiazepines have been found to be the most efficacious pharmacologic agents for dealing with preoperative anxiety.^{327–329} Short-acting agents such as triazolam in teens and adults and midazolam in children provide anxiolysis and sedation which tend to reduce intraoperative anesthetic requirements, but do not appreciably lengthen the in-office recovery period.^{330,331}

It has also been reported in some studies that parental presence during induction of anesthesia (PPIA) can decrease preoperative anxiety in children.³³² In the oral and maxillofacial surgery office a practical approach to this practice is to allow parental presence until venipuncture has been accomplished and midazolam has been administered. If the patient does not appear to be adequately sedated to enable parental separation, 10–20 mg of propofol can be administered slowly to achieve the desired level of sedation.³³³ At this point, the patient is in a state of anxiolysis and sedation such that the parent can leave the operatory.

Preparation for venipuncture

Painful medical procedures such as venipuncture, dental care, immunization, and minor emergency department procedures such as laceration repair are a significant portion of the average child's experience

with painful events.^{334–337} If there is inadequate relief of the pain and anxiety which children experience during painful medical procedures, their experiences may have long-term (or even life-long) negative effects on pain tolerance and pain response.³³⁸ Consequently, it is essential that the oral and maxillofacial surgeon appreciates the potential long-term effects of a painful venipuncture experience, especially in children. These effects have been widely addressed in the medical literature in such fields as emergency medicine, immunology, diabetology, and allergy, all of which require frequent needle injections. Several methodologies have been extensively investigated including nitrous oxide, vapocoolant sprays, and topically applied anesthetics.

Nitrous oxide analgesia has long been used in dentistry and oral and maxillofacial surgery as well as other medical specialties³³⁹ to prepare patients for either venipuncture or intraoral injections. Although it is of some benefit, its weak analgesic properties limit its effectiveness. However, in combination with vapocoolant sprays or topical anesthetics, nitrous oxide has been found to be effective.^{340,341}

In teens and adults, a lengthy wait for a topical anesthetic to take effect in preparation for venipuncture creates scheduling problems.³⁴² Consequently, for these patients most surgeons who use a topical anesthetic prior to venipuncture tend to rely on a vapocoolant. In the past, the most popular agent has been ethyl chloride,^{343–345} but some studies have provided conflicting results as to the efficacy of coolant sprays.^{346,347} However, in recent years there has been renewed interest in the vapocoolant approach, and several new coolant sprays are now available.^{348,349} They have been extensively investigated with randomized double-blind studies. In such a study reported in 2008, a vapocoolant containing 1,1,1,3,3-pentafluoropropane and 1,1,1,2-tetrafluoroethane quickly and effectively reduced pain due to intravenous cannulation and improved the success rate of cannulation. This latter study addressed problems with some prior studies in which application time was more limited. The investigators suggested allowing 5–10 seconds of application of the spray and that the cannulation be attempted within 60 seconds of spray application.³⁵⁰ The author has found a similar approach with ethyl chloride to be effective.

In children, complete elimination of the pain of injection is preferable using topical anesthetics such as EMLA (eutectic mixture of local anesthetic). Adequate anesthesia, sufficient for intravenous cannulation, requires a thick layer³⁵¹ with a contact time of at least 1 hour (preferably 90 minutes)^{352–354} under an occlusive dressing^{355,356} (e.g. Tegaderm®, 3M Health Care, St. Paul, MN 55144). The depth of penetration is approximately 3–5 mm and the duration of action approximately 1–2 hours.^{355,357} Precannulation topical anesthetic application has been investigated extensively both in the US and abroad with positive results in the vast majority of studies.^{356,358–360} EMLA in com-

bination with nitrous oxide can yield a virtually pain-free venipuncture experience for children, with a high approval rating from both parents and children alike.

NPO status

Up until the last 20 years, 8 hours was considered the appropriate NPO period. However, for surgeries scheduled later in the morning or during the afternoon, the old guideline of “nothing after midnight” yields an excessive period of inadequate fluid intake. Consequently, in 1999 the ASA released new guidelines allowing consumption of clear liquids up to 2 hours before administration of anesthesia.³⁶¹ This latter guideline has been followed over the last decade and does not appear to have produced an increase in the incidence of aspiration. However, the patient must be warned that clear liquids does not include pulp-containing juices, such as orange juice, or fluids with fat globules, including milk products.

Delivery system

As discussed above, propofol has now largely replaced methohexital as the preferred major hypnotic agent for total intravenous anesthesia in OMFS offices. Although most anesthesiologists in hospitals and outpatient surgery centers administer propofol by an infusion pump,²⁹⁶ the majority of oral and maxillofacial surgeons tend to use the time-honored incremental bolus or “bump” technique which they have used for several decades with methohexital. However, infusion pumps are slowly increasing in

popularity²⁹⁵ and are receiving coverage at such major meetings as the Anesthesia Update which accompanies the AAOMS Annual Meeting.³⁶²

It is beyond the scope of this chapter to provide an in-depth discussion on the various infusion pumps and their operation. Rather we will briefly describe some of the general principles in setting up and using an infusion pump for the administration of a propofol-based anesthetic. The pump illustrated is the Baxter Infus O.R. Pump used by the author. This partial analog device has been used widely in hospitals and outpatient surgery centers over the last 10–20 years (see Fig. 6b.23).

The author’s technique calls for placement of a three-way stopcock on the 60ml pump syringe, with a conventional (30 inch) intravenous extension tubing attached (Fig. 6b.29a). The three-way stopcock allows additional propofol or remifentanyl to be added to the syringe during surgery without having to remove the syringe from the pump. In addition, at the end of the case, 5ml of saline can be placed in the syringe through the stopcock. Once the pump has restarted, the saline pushes the propofol in the extension tubing into the running intravenous line so that no propofol is wasted. The latter can be helpful if only a small amount of propofol is required at the end of the case during removal of the last tooth. The conventional short anesthesia extension (Fig. 6b.29b) is used for two reasons. The first is its short length and large bore which enable visualization, and thereby detection of crimping. In addition, it is less likely to become crimped because of its larger diameter and wall thickness.

Fig. 6b.29 (a) A three-way stopcock is placed between the pump syringe and the extension tubing. It enables the addition of more propofol, remifentanyl or saline during the surgical procedure. (b) The pump is borne by an anesthesia extension arm attached to the light pole of the operating chair. This eliminates the need for a separate IV stand. The conventional extension is in full view to allow monitoring for kinking.

Converting the patient's weight in pounds to kilograms provides an opportunity to incorporate gender compensation in the rate at which the propofol is administered. It has been well demonstrated that women require higher dosages of propofol, and some have suggested that propofol dosage should be increased by approximately 10–15% in women.^{159–161} The conventional method of converting pounds to kilograms is dividing the patient's weight in pounds by two and subtracting 10%. For women the weight in pounds can be divided by 2 without subtracting 10%. This then yields a body weight approximately 10% higher than the rate determined for a male patient.

The intravenous extension catheter from the pump is placed into the infusion port of the main intravenous catheter as illustrated in Fig. 6b.29b. The syringe used for the incremental boluses of ketamine can then be placed in the same administration port immediately adjacent to the extension catheter used for administration of the propofol. The dosages used for propofol and ketamine are listed in Box 6b.1. Using the combination of propofol and low-dose ketamine, the rates of administration of propofol can be kept at the lower end of the dosage range administered by the pump. Even when a patient is somewhat resistant to medication, it is usually only necessary to increase the rate by 1–2 levels on the pump. This still results in a rate below the "average rate" delivered by the pump. These settings are in keeping with the findings that propofol and ketamine have additive effects in total intravenous anesthesia, i.e. less propofol is required for hypnosis because of the addition of the dissociation which attends the administration of ketamine.

Fig. 6b.30 A piece of sterilization tubing is taped to the face of the pump so that pump adjustments can be made with a gloved hand during the procedure without breaking scrub.

Another adjunct which can be quite helpful in office-administered anesthesia is use of a sterile barrier to enable pump adjustment by the operator–anesthetist. The barrier used by the author is illustrated in Fig. 6b.30. It is made from a piece of sterilization tubing which is cut into 12-inch lengths. These are sterilized and then affixed to the base of the pump at the top and bottom with tape. Then, when adjustment of the pump becomes necessary, the surgeon can quickly adjust the pump without breaking scrub.

Airway management

During intravenous anesthesia airway maintenance is essential. In office-based anesthesia intubation is rarely employed, and other methods of airway maintenance must be used. This had traditionally consisted of either head tilt–chin lift or jaw thrust. In patients with significant obesity, retrognathia, or otherwise compromised airways, head tilt–chin lift and jaw thrust may provide inadequate airway maintenance. A simple intervention requiring no special equipment is the placement of a tongue traction suture (Fig. 6b.31) similar to that which has been used for maxillofacial trauma in the past. A double 3-0 chromic or silk suture is placed through the dorsum of the tongue at the junction of the middle and anterior thirds. The sutures are secured with a Kelly hemostat and the hemostat placed at the contralateral commissure. The traction brings the tongue forward, away from the posterior pharyngeal wall and maintains the airway.

Another intervention is placement of a nasopharyngeal catheter ("trumpet"). However, depend-

Fig. 6b.31 Tongue traction suture for airway maintenance. (a) Using the routine suture material for closure two sutures are passed through the dorsum of the tongue at the junction of the anterior and middle thirds near the midline. (b) The sutures are secured with a Kelly hemostat which drapes over the corner of the mouth at the commissure.

ing upon the patient's anatomy and the particular brand of catheter, the catheter may be too short and the tip may not pass behind the tongue.³⁶³ Thus airway maintenance may remain inadequate. Consequently, the tip of the tube should be visualized with a Weider retractor to assure that it indeed passes behind the tongue.

The LMA or laryngeal mask airway has gained popularity for both emergency airway intervention as well as administration of tube-delivered anesthesia.³⁶⁴ Since the LMA passes through the oral cavity, the conventional design may be cumbersome for oral and maxillofacial surgery procedures. During recent years a smaller-diameter "armored" tube (the LMA Flexible,[®] LMA North America, Inc., San Diego, CA) has been developed which is smaller, more flexible, and interferes less significantly with surgical access.

A final airway intervention is a mandibular traction wire placed around the mandibular posterior teeth (Fig. 6b.32). The latter allows translation of the mandibular condyle anteriorly during the surgical procedure. As the condyle translates forward, the attachment of the tongue attachments are brought forward with it, and the tongue is displaced anteriorly from contact with the posterior pharyngeal wall. In addition, this mandibular anterior positioning can facilitate access for surgical procedures in the mandibular ramus, such as monocortical ramus grafts used in implant reconstruction.

Monitoring

In the historical overview at the beginning of the chapter, it was noted that oral and maxillofacial surgeons adopted advanced monitoring techniques during the latter part of the 20th century.³⁷ Analysis of closed claims in anesthesia suggest that advanced

monitoring, such as pulse oximetry and capnography may prevent a significant percentage of anesthetic mishaps^{365,366} and anesthetic mortality.³⁶⁷ Standard monitoring would include blood pressure, pulse, EKG, pulse oximetry, and a monitor of respiration. The latter has traditionally included observation of chest excursions, movement of air in the anesthesia bag of the anesthesia machine, and use of a pretracheal stethoscope for monitoring breath sounds.^{368,369} However, within recent years capnography, or measurement of end-tidal carbon dioxide (ET-CO₂) has gradually increased in popularity.^{370,371} The capnograph uses infrared (IR) absorption spectrophotometry, based on the principle that certain gases (here carbon dioxide and water vapor) absorb IR light. As light is passed through the respired gases, the amount of IR light absorbed is proportional to the carbon dioxide present during the various phases of respiration.³⁷² There are two common IR analyzers in use, mainstream and sidestream. With mainstream capnography the detection chamber is placed at the end of the patient's endotracheal tube. These are commonly found in closed-system anesthesia machines used in inpatient surgery.³⁷³ The second type of analyzer is a sidestream analyzer which consists of a tube which aspirates a gas sample from the airway and diverts the gas through a sampling tube to an IR detector for analysis.³⁶⁷ The sampling tubes are susceptible to contamination by water, secretions, and occlusion of the tubing.³⁷² However, they can be easily modified and used in non-intubated patients³⁶⁷ such as those treated in an oral and maxillofacial surgery office (Fig. 6b.33).

The capnograph displays a continuous wave form of carbon dioxide data throughout the inspiratory and expiratory phases of respiration (a capnogram). In addition, it reports a numeric percentage value for the respired CO₂ (Fig. 6b.34). In an open system such as that used in oral and maxillofacial surgery, the absolute CO₂ value has little meaning. However, the trend of the wave form can be interpreted to assess events of essential importance, such as the sudden decrease in ET-CO₂ pressure which is indicative of airway obstruction³⁷⁴ or apnea.³⁷⁵ If the wave form becomes rounded with loss of the plateau, bronchospasm is a possible etiology.³⁷²

Capnography provides a more sensitive monitor of respiratory function than does pulse oximetry. However, although capnography rapidly signals that a significant respiratory event has taken place, it provides marginal information regarding the type of event. From this standpoint the traditional pretracheal stethoscope provides more information,³⁶⁹ and in real time.³⁷⁶ In the past some operators have considered the presence of the monitoring tube affixed to the ear as being cumbersome. Consequently, amplified pretracheal stethoscopes have been developed,^{377,378} and the more recently introduced of these use "Bluetooth technology" which allows a remote monitor either for

Fig. 6b.32 The mandibular traction wire – a 26 gauge stainless steel wire ligature is passed between the first and second molar teeth to the medial aspect of the mandible. It then passes lingual to the posterior teeth and finally to the buccal again between the first premolar and cuspid. The ends are twisted together and traction is placed on the mandible with a wire twister. The latter allows translation of the mandibular condyle anteriorly during the surgical procedure.

Fig. 6b.33 (a) Capnographic sidestream analyzer tubing. The tip is placed within the right naris. (b) Detail of the tubing illustrating contouring of the end of the tubing and protection with paper tape to prevent plugging with nasal secretions and occlusion by the nasal mucosa. the ear or a separate speaker which can be heard throughout the operatory (Fig. 6b.35).

Regardless of whether the stethoscope is the conventional tube-to-ear variety or amplified, the information which the apparatus provides is invaluable. When secretions, blood or irrigating fluid collect above the larynx, their presence is indicated by a gurgling sound. If the patient is developing a bronchospasm with wheezing and/or ronchi, these adventitious sounds can be readily appreciated.^{379,380}

Capnography has gained popularity in large part due to the inadequacies of pulse oximetry to truly monitor respiratory status in real time.³⁸¹ Pulse oximetry is based on differential absorption of red and infrared light by oxygenated and reduced hemoglobin (Lambert-Beer Law).³⁸² Oxyhemoglobin (HbO₂) absorbs more infrared light (960nm), while deoxyhemoglobin absorbs more red light (660nm). Thus deoxyhemoglobin appears to be somewhat blue, or cyanotic, even to the naked eye. The change in light absorption during arterial pulsations forms the basis for oxygen saturation measurement.³⁷⁴ Unfortunately, attempting to monitor the respiratory status of the patient with isolated pulse oximetry leads to a false

Fig. 6b.34 The capnographic display with a typical trend tracing and the CO₂ value. In this setting the tracing provides the essential monitoring information and the absolute CO₂ value has little meaning. (Photo courtesy of Henry Bennett, DDS, Davis, CA.)

Fig. 6b.35 Bluetooth technology allows a remote monitor for the precordial stethoscope to either the ear or a separate speaker. (Reproduced with permission of Surgical Solutions USA.)

sense of security.³⁸³ Due to the sigmoidal configuration of the oxygen-hemoglobin dissociation curve³⁸⁴ (Fig. 6b.36), a decrease in oxygen saturation from 100% to 90% can easily represent a drop in pO₂ from 100mmHg to almost 60mmHg.³⁸⁴ In addition, there is a time lag in the depression of oxygen saturation between peripheral arterial blood and central arterial blood.³⁸⁵ Due to the limitations of pulse oximetry, investigation into the monitoring of respiratory status resulted in the development of capnography.

Although capnography may be a more sensitive monitor of respiratory status than pulse oximetry, there has been considerable controversy as to whether its use should be considered a standard of care.^{386,387} As yet neither capnography nor auscultation with a pretracheal stethoscope is considered an essential parameter of care in the AAOMS Parameters of Care document.⁵⁰ Each is considered an alternative within a list of five entries including: observation of chest wall excursion, pretracheal stethoscope, observation of the reservoir bag, monitoring of skin mucosa, nail beds and surgical site, and monitoring of expiratory gases such as ET-CO₂.

In the mid-1990s BIS (bispectral index scale) was introduced as a new form of monitoring, based on the electroencephalogram (EEG). This BIS value is

Fig. 6b.36 The oxygen-hemoglobin dissociation curve at pH 7.40 and temperature 38°C. As the oxygen saturation decreases below 90, note the precipitous drop in pO₂. (Reproduced from *Review of Medical Physiology* (Ganong WF, ed.), 22nd edn. New York: McGraw-Hill, 2005. With permission of the McGraw-Hill Companies.)

derived from a combination of the conventional analysis of the EEG using fast Fourier transformation and the interfrequency phase relationships among the underlying sinusoidal components of the EEG.³⁸⁸ An algorithm is used to integrate the two into a proprietary parameter termed the bispectral index.^{389,390} The latter is a dimensionless number which is scaled from zero to 100. A value of 100 represents the EEG of an awake individual, and zero represents complete electrical silence or cortical suppression. The various measured parameters have been integrated into this single variable. It is proposed that BIS values of 65–85 correspond to sedation and values of 40–65 to general anesthesia (Figs 6b.37–6b.39).³⁷⁴ This was derived by measurement of clinically relevant sedative end points and hypnotic drug concentrations in a cohort of anesthetized volunteers.³⁹¹ The algorithm has been revised on several occasions in an attempt to achieve maximal clinical relevancy.

Overall the BIS value is an indication of the potential for awareness and the hypnotic level of the patient to avoid hypnotic overdose.^{392,393} It cannot predict movement or hemodynamic response to stimulation, nor can it truly predict the exact moment at which consciousness returns.³⁸⁸ Since ketamine exhibits excitatory effects on the EEG, BIS cannot be used to accurately monitor hypnosis during ketamine anesthesia.³⁹⁴ However, when ketamine is used in conjunction with propofol, there is an additive interaction which can lead to hypnotic end-points detected by BIS.³⁹⁵ The reliability of BIS as a tool to prevent intraoperative awareness has been debated in the literature.³⁹⁶ Some studies indicate that it is efficacious, while others do not. The concept is an intriguing one, and it is possible that further refinement of the algorithms which form the basis of the BIS indicator will ultimately provide an indicator of unquestioned reliability.

Fig. 6b.37 Typical electrode placement on the forehead for the BIS monitor. (Photograph courtesy Robert Mraule, DDS, MD, Salinas, CA.)

Fig. 6b.38 Typical display pattern on the BIS monitor.

Several studies have appeared in the oral and maxillofacial surgery literature reporting the use of BIS to monitor intravenous anesthesia for oral and maxillofacial surgery procedures. These studies indicated that use of BIS tended to result in a reduction in anesthetic requirement.^{397–400} However, the expense of the disposable electrodes (\$15–20 per patient) have tended to limit use of the technique.

Fig. 6b.39 Correlation of BIS values with level of consciousness. (Reproduced from *Miller's Anesthesia* (Miller RD, ed.), 6th edn. New York: Elsevier/Churchill Livingstone, 2005; 1253, Fig. 31–21 by permission. Copyright © 2005 Elsevier.)

It must be remembered that intraoperative monitoring does not in itself prevent accidents. Rather, Eichhorn has suggested that monitoring standards “have initiated and provoked behavior patterns of thinking and use of equipment in such a way that intraoperative anesthesia accidents have been prevented”.⁴⁰¹

Awareness during anesthesia

As discussed in the previous section, the reliability of BIS to predict intraoperative awareness has been questioned. Unfortunately, there appears to be no tool which provides absolute reliability in determining awareness. The incidence of patients temporarily regaining consciousness or remaining conscious during surgical procedures has been estimated to be approximately 1 case in 2000.⁴⁰² Studies of closed claims reveal that the anesthetic techniques most commonly associated with awareness are those using opioids with muscle relaxants. However, several studies have suggested that awareness is also more likely to occur with nitrous oxide and intravenous agents such as propofol, barbiturates, benzodiazepines, and opioids.⁴⁰³

Prudent prevention strategies for awareness include the use of at least small doses of amnesic drugs such as midazolam and ketamine, as well as avoiding voicing negative or derogatory remarks about the patient or prognosis during surgery.⁴⁰⁴ However, the effects of amnesic agents are predominantly anterograde, and administering the agent after the patient becomes aware is usually of little benefit.⁴⁰⁵ It has also been maintained that awareness under intravenous anesthesia with propofol is far less

likely as long as a constant infusion is maintained with a pump.⁴⁰⁶

The ASA established a task force on intraoperative awareness which reported its findings in 2006.⁴⁰⁷ It concluded that conventional monitoring systems for EKG, blood pressure, heart rate, and ET-CO₂ are valuable to help assess intraoperative consciousness. The task force was equivocal in regard to the use of such monitors as BIS. They also were equivocal regarding the benefit of benzodiazepines in all patients.⁴⁰⁷

Intraoperative fluid management

Historically intravenous access in oral and maxillofacial surgery was provided with straight needles and butterfly-type needles and cannulae without a continuous intravenous infusion. However, the rigid hollow-bore needles were far more likely to cause vein laceration and infiltration than indwelling plastic catheters. Laceration and extravasations of fluid are particularly problematic in areas of extremity mobility such as the antecubital fossa, the wrist, or dorsum of the hand.¹⁴⁰ Over the last 10–20 years it has become common practice for oral and maxillofacial surgeons to use indwelling plastic catheters and provide a continuous intravenous infusion during the perioperative period.

Another change which has taken place within recent years is the nature of the fluid used for intravenous fluid replacement and rehydration. In the past the preferred maintenance fluid was 0.45% normal saline in 5% dextrose (D5/.45).^{408,409} However, it has been shown that the dextrose in such solutions is rap-

idly metabolized, which effectively results in the administration of a hypotonic infusion fluid. Consequently, it is now recommended that maintenance fluids in outpatient surgery consist of an isotonic solution such as normal saline.¹⁴⁰

Since patients must be NPO for their procedures, there is a fluid deficit which continues throughout the perioperative period. In the past, perioperative fluid administration was maintained at a relatively low volume of 1–2 ml/kg. However, studies over the last decade have demonstrated that higher volumes of 15–20 ml/kg are highly beneficial.^{410–412} With the higher rehydration rate, patients have fewer complaints of headache, nausea, vomiting, fatigue, light-headedness, dizziness, and thirst.⁴¹³

Recovery and discharge

With the shorter-acting agents currently employed, such as propofol, ketamine, and remifentanyl, recovery and discharge can take place in either the operating room or a separate recovery area. Regardless, patients should not be discharged until they can be safely transported home and continue to be safely monitored by their non-medical family member or escort. To assure that patients are not prematurely discharged, postanesthetic recovery scores have been developed. The first to gain wide acceptance was developed by Antonio Aldrete at the University of Colorado Medical Center in 1970.⁴¹⁴ The concept of scoring was patterned after the Apgar Scoring System developed by Dr Virginia Apgar for evaluation of neonates.⁴¹⁵ Aldrete's scoring system took into account five categories of recovery issues including activity, respiration, circulation, consciousness, and color (Table 6b.3). The system has been widely used in outpatient surgery and in oral and maxillofacial surgery for several decades.

A more recent alternative discharge scoring system for ambulatory surgery was developed by Frances Chung from the Toronto Hospital in Ontario, Canada in the mid-1990s.^{416–418} Its scoring categories include vital signs, activity level, nausea and vomiting, pain, and surgical bleeding (Table 6b.4). The criteria in this scoring system have greater relevance in oral and maxillofacial surgery than do those of the Aldrete score.

Special patient populations

In the interest of patient safety, a thorough preoperative evaluation should be performed for all patients. However, there are subgroups of patients who present risks which require special diligence in their preoperative evaluation and intraoperative management. These include pediatric and geriatric patients, those with a potentially compromised airway (e.g. the morbidly obese and patients with sleep apnea) and medically compromised patients.

Pediatric patients

For many pediatric patients and their parents surgery in general, and oral and maxillofacial surgery in particular, is a decidedly anxiety-laden experience.³²⁵ If inadequately managed, this anxiety can make treatment exceedingly difficult for all involved, or indeed result in failure to complete the planned treatment. The two primary methods of dealing with patient and parent anxiety include premedication with an anxiolytic (usually midazolam)⁴¹⁹ and/or parent presence prior to induction of anesthesia (PPIA).^{420–424} A review of the literature suggests that when viewed as isolated approaches, premedication is probably more efficacious than parental presence.⁴¹⁷ However, some studies suggest that a combination of the two is more effective than either used independently.²³² With an adequately prepared parent at the patient's side, the parent can help distract the patient while the venipuncture is accomplished. In addition, the nitrous oxide mask helps to obscure the child's vision while venipuncture is in progress.

A particularly helpful development for pediatric patients has been the introduction of topical anesthetics such as EMLA for venipuncture. As discussed above, the EMLA must be left in place for at least 60–90 minutes to assure a painless injection. In addition, EMLA should be applied to an alternative venipuncture site in the event that the first attempt is unsuccessful. In combination with oral premedication, EMLA enables pediatric patients to progress through their treatment without any memory of painful injections. With the intravenous route established, the surgeon can titrate anesthetic agents, rehydrate the patient and have the intravenous route available in the event of an anesthetic or medical emergency. Various other approaches such as intramuscular injections, rectal suppositories, nasal sprays, etc. have been used. However, none have as high level of patient acceptance or safety as does the combination of oral premedication and establishment of the intravenous route with topical anesthesia.

For premedication midazolam is the most frequently used agent. It is available in a sweet-tasting elixir form and is given at a dose of 0.5 mg/kg. However, in recent years there has been a resurgence of interest in the α_2 agonist clonidine for anesthesia premedication in children. Studies from multiple centers in the US and abroad suggest that in an oral dose of 4–5 μ g/kg clonidine provides not only sedation equivalent to midazolam, but reduction of PONV, reduction of anesthetic requirements, post-operative analgesia, and no untoward effect on respiration.^{425,426} Clonidine will be discussed further in the section "Future trends and advancements – on the horizon", at the end of the chapter.

The primary anesthetic agents, propofol and ketamine, have particular efficacy in children. However, one must be mindful of the more rapid redistribution of these agents in the pediatric population.

Consequently, larger doses on a weight-for-weight basis must be used. Ketamine has been found to be far more efficacious in pediatric populations than in older patients. However, it carries with it the side-effect of hypersalivation, and an appropriate antisialogogue such as glycopyrrolate should be used. The glycopyrrolate tablet can be broken into appropriate dosage segments and crushed into a fine powder which can be administered along with the sweet-tasting benzodiazepine elixir, triazolam or clonidine in pulpless fruit punch.

In teens and adults, the initial low dose bolus of ketamine is often all that is required during the intravenous anesthetic. However, with children small incremental boluses of 2.5–5 mg can be administered every 10–15 minutes to ensure that the patient has sufficient dissociation throughout the procedure. In addition, ketamine has been shown to help preserve functional residual capacity in younger children, which provides an element of safety.⁶⁴

Geriatric patients

Oral and maxillofacial surgeons are seeing an ever-increasing number of geriatric patients in their practices. As discussed above, these patients require certain modifications in the normal routine of intravenous anesthesia. Virtually all of the agents used must be administered in lower doses, often at levels of 50% or less with progressive age. Dose guidelines for propofol are outlined in Table 6b.1.

In the past, midazolam and other benzodiazepines have been used fairly extensively in the treatment of the elderly. They were viewed as being the "safest" agents because of the minimal cardiovascular and respiratory depression with which they are associated. However, there is a growing body of literature which suggests that anesthesia, including outpatient anesthesia similar to that used in oral and maxillofacial surgery offices, can be associated with cognitive dysfunction following surgery. Fortunately, the incidence of cognitive dysfunction appears to be smaller in the "day care" setting.⁴²⁷ It often resolves within 3 months in middle-aged patients,^{428,429} but can be distressingly persistent.

Of the agents in common use, the benzodiazepines are those which have the most profound effects on memory. Amnesia to the surgical event is usually considered a desirable quality of an agent. However, if this impairment of memory persists for long periods following the procedure, the desirable effect becomes an undesirable one. As an appreciation of long-term cognitive dysfunction in older patients has increased among anesthesiologists, many have markedly reduced dosage levels of benzodiazepines or eliminated them altogether (personal communication, Andrew Herlich, DDS, MD). Without a benzodiazepine, there is a somewhat greater likelihood that the patient will experience awareness during the surgical procedure. This should be addressed with the

patient and family prior to the procedure, with assurance that the reason is to prevent any long-term memory effects. Most elderly patients and their families would prefer to have some awareness as opposed to long-term memory effects.

Patients with compromised airway

At the preoperative consultation, evaluation of the airway is essential. Several different guidelines have been developed including the Mallampati score,⁴³⁰ the upper lip bite test (ULBT),⁴³¹ and submandibular measurements from the hyoid bone and thyroid cartilage and sternum to the anterior mandible. The Mallampati criteria and ULBT are illustrated in Figs 6b.40 and 6b.41. Clinical measurements which have been used include the thyro-mental distance, which should be at least 5cm (three wide finger breadths),⁴³² the sterno-mental distance which should be greater than 12.5cm and the hyo-mental distance of approximately 6cm.⁴³³ A neck circumference greater than 43cm (17 inches) has been associated

with a compromised airway and difficult intubation.⁴³⁴ Another critical measurement is the extent of mouth opening as measured between the maxillary and mandibular incisors which should be at least 30–40mm.⁴³⁵ In the literature various authors have commented on the inadequacy of any of these tests and measurements taken independently. However, a composite of several of them is usually considered to yield a predictability of approximately 80%.⁴³⁶

Although airway difficulties may be seen in a variety of settings, special care must be taken in the management of the airway in patients who are morbidly obese or suffer from obstructive sleep apnea (OSA).⁴³⁷ Patients should have the body mass index (BMI) calculated: $BMI = \text{wt. in kg} \div \text{ht. in m}^2$ or $BMI = (\text{wt. in lbs.} \div \text{ht. in inches}^2) \times 703$ and categorized (see Fig. 6b.42).^{438,439} Many feel that patients who have a BMI of greater than 35 may not be acceptable candidates for anesthesia in an office setting.⁴⁴⁰ Sleep apnea often goes undiagnosed or patients may exhibit denial.⁴⁴¹ A valuable screening tool for OSA is the STOP-Bang Scoring Model developed by Chung *et al.* from the Department of Anesthesia at the University of Toronto.⁴⁴² The questionnaire is illustrated in Table 6b.5.

There are several precautions which should be taken in the treatment of morbidly obese patients and patients with sleep apnea. The surgeon should consider performing the procedure with the patient in a semi-upright position. In choosing a blood pressure cuff for these patients, one should choose a cuff with a width greater than one third the circumference of the arm.⁴⁴³ When narrower cuffs are used, a false high systolic blood pressure will be recorded. Close attention to the airway is essential and airway adjuncts such as a tongue traction suture or nasopharyngeal airway may need to be considered. In general, anesthetic and sedative medications should be dosed according to lean body mass as opposed to total body weight. Short-acting medications, such as propofol and low-dose ketamine and remifentanyl, are preferred.⁴⁴⁴

The medically compromised

A comprehensive discussion of medical compromise as it affects anesthesia is beyond the scope of this chapter. However, a valuable tool in the management of these patients is use of faxed medical clearance correspondence. When the clinician encounters aspects of a patient's medical compromise which can influence anesthesia and surgery, a succinct faxed letter should be sent to the patient's physician regarding appropriate management. The surgeon's attempting to contact the physician by phone is often problematic because of scheduling problems in both offices. The fax provides unequivocal written clearance which is dated and timed as opposed to verbal clearance that can be misconstrued or denied.

Fig. 6b.40 The Mallampati classification. The patient is instructed to open his mouth maximally and to protrude his tongue as far as he can. (Reproduced from *Clinical Anesthesiology* (Morgan GE, Mikhail M, Murray M, eds.), 4th edn. New York: McGraw-Hill, 2006. With permission of the McGraw-Hill Companies.)

Fig. 6b.41 The upper lip bite test. The patient is instructed to protrude his mandible as far as he can and to bite into the upper lip. (Reproduced from Khan Z, Kashfi A, Ebrahimkhani E. A comparison of the upper lip bite test. *Anesth Analg* 2003; 96: 595–9 by permission. Copyright © 2003 Lippincott Williams & Wilkins.)

In some states, such as California, the status of faxed documents as evidence has been addressed by both legislation and the courts (California Civil Code: 1633.13 and 1633.14, California Evidence Code 1420 & 1421). In addition, the California Court of Appeals held in *Hoffer V. Young*, 38 Cal. App. 4th 52(1995), that a fax was just as good as sending a letter.

When the initial communication is verbal by phone, a confirming fax can be used to document the discussion. Thus the verbal communication is converted into a form of written communication

which serves as far better documentation than the handwritten notes regarding the conversations that are entered by the surgeon in the patient's chart (personal communication, Arthur Curley, JD, Larkspur, CA).

Patients who are at a high level ASA III classification are generally not considered to be acceptable candidates for treatment in an office setting.¹⁴⁰ In such cases it is prudent to consider treatment of the patient in an outpatient surgery center or hospital setting.

High risk of OSA: answering yes to three or more items

Low risk of OSA: answering yes to less than three items.

Future trends and advancements – on the horizon

Unquestionably propofol has dramatically changed outpatient anesthesia in many ways. However, one of its major drawbacks is its insolubility in water which has made it necessary for it to be formulated in a liquid emulsion.⁴⁴⁵ Consequently, a water-soluble pro-drug of propofol termed “fospropofol” has now been formulated.⁴⁴⁶ Initial studies indicate that the drug has a somewhat longer time to peak concentration after bolus^{148,445} and a longer half-life. Initial studies have disclosed no major disadvantages to the formulation and even suggest that there may be a tendency for fewer and shorter duration of periods of apnea.⁴⁴⁷

Like propofol, remifentanyl has suffered from stability and preparation problems. Currently the smallest vial marketed is 1 mg of the remifentanyl powder.¹⁰⁴ Since the agent is so potent, this is sufficient agent for the treatment of 15–20 patients. However, the manufacturer states that the solution is only stable for 24 hours.⁴⁴ In most office and outpatient surgery center settings, this frequently leads to considerable waste. Although the problem has been brought to the attention of the manufacturer, smaller vials have not as yet been offered.

Interestingly the α_2 agonist clonidine, originally developed as an antihypertensive,⁴⁴⁸ has been shown to have application for anesthesia premedication, especially in pediatrics. It was introduced for this purpose in 1993 by Mikawa and co-workers.⁴⁴⁹ The agent provides anxiolysis, sedation,^{425,426} enhancement of postoperative analgesia,⁴⁵⁰ as well as reduction of shivering⁴⁵¹ and PONV. However, there were a few negative side-effects such as bradycardia, hypo-

tension or respiratory depression.⁴⁵² Bergendahl *et al.* suggest that the reason for clonidine's lack of routine use in clinical practice is due to the fact that there are multiple generic preparations available. Therefore, there is no financial inducement for the pharmaceutical industry to promote the drug.⁴²⁵

A second α_2 agonist, dexmedetomidine, is eight times more specific for the α_2 receptor than clonidine.^{127,453} The new agent has now been studied as a sedation agent for third molar surgery. Heart rate and blood pressure during surgery were somewhat lower in the dexmedetomidine group and there was less amnesia as opposed to the midazolam group.^{454,455} Since the drug is currently quite expensive, it is likely that its use for third molar surgery will be limited until it becomes available in generic form.

There are two intriguing medications which are awaiting approval in the US by the Federal Drug Administration. The first of these is hardly "new" in Europe, where it has been in use for sometime. This is the S+ enantiomer of ketamine.^{134,205} Of the two isomers it appears to have superior properties, including greater potency, as well as more rapid effect and redistribution. Unfortunately, it has not been found to be without some of the psychotomimetic and cardiovascular side-effects of the racemic mixture.²³⁴ Those using the agent in Europe appear to prefer the S+ isomer variant to the racemic mixture, and it is hoped that FDA approval will be forthcoming.

An especially interesting new drug is sugammadex, a polydextran compound which has been found to encapsulate the non-depolarizing muscle relaxant rocuronium.^{456,457} Anesthesiologists and oral and maxillofacial surgeons have long sought a replacement for the polarizing muscle relaxant succinylcholine. Amongst several undesirable properties are its role as a potential triggering agent for malignant hyperthermia and its tendency to cause bradydysrhythmias.⁴⁵⁸ Alternative non-depolarizing agents such as rocuronium have a far longer duration of action, which make them somewhat impractical for treatment of laryngospasm. However, through encapsulation sugammadex totally inactivates rocuronium quite rapidly. Consequently, rocuronium could then be used just as effectively as succinylcholine for reversal of laryngospasm without the significant liabilities of succinylcholine.⁴⁵⁹ Numerous reports in the literature point to the high safety and lack of adverse side-effects of sugammadex. However, it is still awaiting final approval by the drug administration.

Conclusion

In this chapter we have watched the evolution of anesthesia in oral and maxillofacial surgery from the "one man show" which was Gardner Quincy Colton in the mid-19th century to state-of-the-art outpatient anesthesia practice which exists in oral and maxillo-

facial surgery practices throughout the US today. As we have seen, the success of oral and maxillofacial surgeons in maintaining general anesthesia and sedation as an integral part of their practices can be largely attributed to organizational efforts within the specialty. The AAOMS is strongly supported by its membership and the organization can effectively coordinate its efforts with other organizations such as the ASA, ADA, ADSA, etc. Surgical anesthesia was first demonstrated by dentists, and oral and maxillofacial surgeons, as dental specialists, have been at the forefront of advancements, such as the development of office-based anesthesia. There is every indication that this pre-eminence in the field of anesthesia will continue as the 21st century continues to unfold.

Chapter 7

Dentofacial Infection

Ashraf Ayoub

This chapter will cover infections of odontogenic origin, including the fascial spaces of the head and neck in which these infections can manifest themselves. The appearance and management of fascial space infections is discussed. Additionally, this chapter will discuss specific infections of the oral cavity and related structures which may be of dental origin. These will include osteomyelitis in various forms, osteoradionecrosis, bisphosphonate-related osteonecrosis of the jaws, cavernous sinus thrombosis, necrotizing fasciitis, actinomycosis, tuberculosis (TB), and syphilis.

Dentoalveolar abscess

The acute dentoalveolar abscess is a localized suppurative inflammation which involves the teeth and the supporting periodontal structures (Fig. 7.1). The pathogenic microorganisms which are predominantly anaerobes normally gain entry to the periapical tissue through the necrotic pulp of carious teeth¹ or via the gingival crevice of the periodontal ligament. The most typical clinical features are severe pain and exquisite tenderness on percussion or touching the tooth during mastication. The pain is due to the local release of inflammatory mediators such as kinins and histamines, and fluid exudates causing increased pressure in the confines of underlying alveolar bone. Pyrexia and lymphadenopathy can be common symptoms associated with this infection. Prompt evacuation of pus by either extracting the tooth or removing the infective pulp reduces the internal pressure and the patient's pain.

The fate of the acute dentoalveolar abscess depends on the number and the virulence of the invading microorganisms, as well as the resistance of the patient. The spread of the infection will be governed by the position of the tooth in the alveolus and rela-

Fig. 7.1 Radiograph of dental abscess.

Introduction

Inflammation, infection, and pus formation were first described in Egyptian papyri. Inflammation is defined as reaction of the tissues to an invasion by pathogenic microorganisms. These reactions tend to destroy and limit the spread of infectious agents and repair the damaged tissues. The inflammatory process involves fluid and cellular exudates in an attempt to destroy and engulf the invading microorganism.

tionship of the apices of the infected teeth to muscle attachments and their relative proximity to the lingual and buccal surfaces of the jaw bones.

Infection originating from a dental abscess may spread to involve the deeper tissues of the head and neck region, once the abscess has broken through the surface (usually buccally) of the alveolar bone. On the other hand, the invading microorganisms may be destroyed by the natural local resistance of the body, prescription of antibiotics, and removal of the source of infection by extraction or endodontic means. The lesion would then resolve. However, in some instances, lack of appropriate treatment may lead to the development of a chronic dentoalveolar abscess where the lesion never heals by itself but persists as a lesion of low-grade virulence, characteristic of the typical granuloma. Chronic dentoalveolar abscesses and periapical granulomas are generally asymptomatic unless, or until, reignited in an acute phase. Only the development of an acute exacerbation would lead to the cardinal signs of inflammation such as tenderness, pain, redness, and swelling. Sinus formation, either intraorally or extraorally, is not an infrequent feature of this chronic infection. The chronic lesion has the potential to stimulate epithelial cells and initiate the development of a dental cyst.

Radiographic appearance

In the acute phase, the earliest changes are thinning of the periodontal space followed by loss of apical lamina dura, then radiolucency with ill defined margins. Chronic abscesses or apical granuloma are usually associated with a well circumscribed radiolucency.

Site and spread of infection

Bone, muscle, aponeurosis or fascia, neurovascular bundles, and skin, can act as barriers against spread of infection. However none of these tissue barriers or boundaries is so restrictive or containing that they necessarily prevent the spread of infection into contiguous anatomic spaces (Fig. 7.2).² The following are the most common routes for the spread of infection from dentoalveolar infections:

- upper lip;
- canine fossa;
- infraorbital region;
- buccal space (5 in Fig. 7.2);
- palate;
- submasseteric (3 in Fig. 7.2);
- retropharyngeal;
- lateral pharyngeal (1 in Fig. 7.2);
- pterygomandibular space (2 in Fig. 7.2);
- infratemporal fossa;
- parotid space;
- buccinator space (4 in Fig. 7.2);
- suprahyoid region;

Fig. 7.2 Direction of spread of infection, and the fascial spaces involved, from the lower third molar site.

- submandibular space;
- submental space;
- sublingual space.

Upper lip

Infection at the base of the upper lip originates from the upper anterior teeth. It spreads on to the orbicularis muscle from the labial sulcus between the levator labii superioris muscle and the levator angularis oris muscle.

Canine fossa

Spread of infection to the canine fossa usually originates from maxillary canine or upper premolar teeth, often presenting above the buccinator muscle attachment. These swellings obliterate the nasolabial fold (Fig. 7.3).

This space is in close proximity to the lower eyelids, and therefore early management is mandatory to avoid circumorbital infection. There is a risk of spread cranially via the external angular vein which may become thrombosed.

Buccal space

The attachment of the buccinator muscle to the base of the alveolar process can control the spread of infection in the region of the mandibular and maxillary molars. The infection spreads intraorally superficial to the buccinator muscle in front of the anterior border of the masseter muscle. Therefore the clinical manifestation of the infection of this space is characterized by swelling confined to the cheek (Fig. 7.4). However, infection may spread superiorly towards the temporal space, inferiorly to the submandibular space or posteriorly into the masseteric space. In some

Fig. 7.3 Clinical infection of the upper teeth spreading to the canine fossa.

Fig. 7.4 Clinical infection of the buccal space.

cases infection may spread to the surface of the skin, leading to fistula formation (Fig. 7.5).

Palate

The palate is usually involved by infection originating from the maxillary lateral incisor or the palatal roots of the posterior teeth. The infection spreads from the apices of these teeth, perforating the palatal alveolar bone, and pus accumulates below the palatal mucoperiosteum (Fig. 7.6). It is important to be aware

Fig. 7.5 Cheek infection secondary to spread of infection from an upper molar.

Fig. 7.6 A palatal abscess from an upper lateral incisor.

that, although the lateral incisor is the commonest source of palatal abscess, most still present labially.

Pterygomandibular space

Infection in this space is manifested by trismus due to the involvement of the pterygoid muscles. This space is bounded medially by the medial pterygoid muscle and laterally by the medial surface of the mandible, anteriorly by the pterygomandibular raphe, and posteriorly by the deep lobe of the parotid gland. The lateral pterygoid muscle forms the roof of this space (Fig. 7.7).

Submasseteric space

The commonest source of infection in this space is from lower third molar pericoronitis. This space is bound medially by the masseter muscle and laterally by the outer surface of the ramus of the mandible (Fig. 7.8). It is in direct communication with the lateral pharyngeal space posteriorly. The temporalis muscle divides the superior part of this space into two portions the superficial temporal space, which is bounded by temporalis muscle medially, and the deep temporal space with the temporalis muscle laterally and the periosteum of the temporal bone medially.

Fig. 7.7 Axial computed tomography (CT) scan of pterygomandibular space infection.

Fig. 7.8 Axial CT scan of a submasseteric abscess.

Severe trismus due to spasm of the masseter muscle is a characteristic feature of involvement of this fascial space.

Infratemporal space

Extension of infection from maxillary molars can pass into this space. Infection may also spread from the pterygomandibular, parotid or lateral pharyngeal region to the infratemporal space. The patient then complains of pain, particularly with mouth opening, some dysphagia, and difficulty with lateral mandibular movements. This space is located behind the zygomatic bone posterior to the maxilla and medial to the insertion of the medial pterygoid muscle. The infratemporal space is bounded superiorly by the greater wing of the sphenoid and is in close proximity to the inferior orbital fissure with a possible risk of spread of infection to the orbit.

Parotid space

Involvement of this space may be an extension of infection from the middle ear or the mastoid region. Infection from the masseteric or the lateral pharyngeal space may also spread to the parotid region. Therefore, the most characteristic feature of involvement of this space is swelling of the parotid gland region below the ear lobe. This space contains several important structures which may be affected by infections. These include the 7th cranial nerve, auriculotemporal nerve, facial vein, the parotid lymph node, and, more deeply, the external carotid with its branches.

Submandibular space

This space is located below the mylohyoid muscle, medial to the ramus and body of the mandible. It is bounded anteriorly by the attachments of the anterior belly of the digastric muscle and posteriorly by the posterior belly of digastric muscle and stylomandibular ligament. Infection from the posterior mandibular teeth may pass lingually below the attachment of the mylohyoid muscle into this space. Clinically, swelling of the submandibular regions tends to obliterate the angle of the mandible, causing pain and redness of the skin overlying this region. Dysphagia is usually a marked symptom (Fig. 7.9).

Submental space

This space lies between the two anterior bellies of the digastric muscle. Anteriorly and laterally this space is bounded by the body of the mandible (Fig. 7.10). It is contained superficially by the platysma muscle and deeply and superiorly by the mylohyoid muscle. The infection of this space usually arises from mandibular anterior teeth where the infection perforates the lingual cortex; swelling of the submental region is a characteristic clinical feature. The skin over the swell-

Fig. 7.9 Clinical picture of submandibular space infection.

Fig. 7.10 Clinical picture of submental abscess.

ing is stretched and hardened, and the patient experiences considerable pain and difficulty with swallowing. The infection may progress buccally causing swelling in the labial sulcus and over the chin.

Sublingual space

Infection spreads into this space as the result of perforation of the lingual cortex above the attachment of the mylohyoid muscle. This space is bounded superiorly by mucous membrane and inferiorly by the mylohyoid muscle. The genioglossus and geniohyoid muscles form the medial boundary. Laterally, this space is bounded by the lingual surface of the mandible. Infection in this space will raise the floor of the mouth and displace the tongue medially and posteriorly. The tongue displacement may compromise the airway and immediate intervention may be required. Dysphagia and difficulty in speech are also common.

Pharyngeal space

This space is located on the lateral side of the neck, bounded medially by the superior constrictor muscle

Fig. 7.11 Axial CT scan of pharyngeal space infection.

of the pharynx and posterolaterally by the parotid space. Infection in this space may originate from mandibular molars or third molar pericoronal supuration. This could also be a site of spread of infection from the parotid space or fascial space around the body of the mandible. The lateral pharyngeal space contains the carotid sheath, glossopharyngeal nerve, accessory nerve, and the hypoglossal nerve, as well as the sympathetic trunk. Therefore, spread of infection into this space carries the significant danger of spread into a descending neck infection and involvement of the mediastinum. Clinically, stiffness of the neck, swelling of the lateral wall of the pharynx, medial displacement of the tonsils, dysphagia, and trismus are among the characteristic clinical features of involvement of this space (Fig. 7.11).

Retropharyngeal space

This space is located between the posterior wall of the pharynx and the prevertebral fascia. This space is in direct communication with the base of the skull superiorly and the mediastinum inferiorly. It has the same characteristic clinical features as infection of the lateral pharyngeal space and carries the significant complication of a descending neck infection.³

Microbiology of dental infections

Recent reports conformed that there is usually a polymicrobial cause for oral/dental infection comprising facultative anaerobes, such as viridans group streptococci and the *Streptococcus anginosus* group, with predominantly strict anaerobes, such as anaerobic cocci, *Prevotella* and *Fusobacterium* species. The use of sophisticated non-culture methods has identified a wider range of organisms such as *Treponema* species and anaerobic Gram-positive rods such as *Bulleidia extructa*, *Cryptobacterium curtum*, and *Mogibacterium timidum*.⁴

Management of patients with orofacial infection

The management of orofacial infection involves surgical intervention to drain localized pus and medical support for the patient.⁵

1. Incision and drainage. This could be carried out either intraorally or extraorally depending on the location of the infection (Fig. 7.12). Aspiration of pus prior to incision allows a more accurate sampling method as it reduces contamination and helps preserve anaerobic bacteria. Fluctuation of the swelling indicates the presence of pus and is defined as fluid transmission using bi-digital palpation.
2. Antibiotics. Antibiotics can be provided empirically or a specific antibiotic given based on culture and sensitivity tests. Penicillin has the potential to be the first-line agent in the treatment of odontogenic infections. Most other beta-lactam antibiotics, including fourth-generation cephalosporins, were not found to have greater effectiveness than penicillin.⁶ Amoxicillin is a useful broad-spectrum drug in this context although many clinicians prefer the specific anti-anaerobic effect of metronidazole.⁷
3. Analgesics. Analgesics provide temporary relief of pain until the causative factors of infection have been brought under control. The choice of analgesic should be based on patient's suitability. Non-steroidal anti-inflammatory drugs are used in mild to moderate pain. Opioid analgesics, such as dihydrocodeine and pethidine, are used for severe pain. Paracetamol, ibuprofen and aspirin are adequate for most mild pain secondary to dental infection. Analgesics need to be given with care, especially when narcotics are used, as they carry the risk of depression of respiration.
4. Identification and elimination of the source of infection. Identification is achieved by both clinical and radiographic assessment. Elimination of the source is by root canal therapy, extraction or periradicular surgery.⁸

Fig. 7.12 Clinical picture of extraoral incision and drainage of a submandibular abscess.

Ludwig's angina

Bilateral involvement of the submandibular, submental, and sublingual spaces with a suppurating infection may lead to diffuse cellulitis classically called Ludwig's angina. This is demonstrated by induration of the swollen skin of the neck, tenderness, elevation of the floor of the mouth, trismus, and dysphagia. The tongue usually shows a varying degree of edema.

The infection of Ludwig's angina may be secondary to the spread of infection from mandibular teeth or penetrating injury to the floor of the mouth. Ludwig's angina is a life-threatening condition which demands emergency treatment.⁹ The treatment procedure consists of:

1. Protection of the airway.
2. Hospitalization and administration of intravenous antibiotics and fluids.
3. Incision and drainage extraorally of the submandibular and submental space with through-and-through drainage when necessary.
4. Relief of pain. This is achieved by incision and drainage in addition to the administration of analgesics.

Identification and treatment of the causative factor, often extraction of an infected lower tooth, is necessary after dealing with the acute condition. Emergency cricothyroidotomy or tracheostomy may be necessary to deal with respiratory obstruction. A tracheostomy may have to be made low down to avoid the infected area and may have to be carried out while the patient is awake due to a tendency to lose the airway in the supine position.

Osteomyelitis

Osteomyelitis means the spread of infection through the soft tissue component or marrow of the bone which may include periosteum, neurovascular bundles, narrow spaces of the spongy bone, and the Haversian systems of the cortical bone. It is more common in the mandible than in the maxilla due to the less profuse nature of the blood supply and the density of the cortical plates of the mandible. The most common cause of suppurative osteomyelitis is an odontogenic infection.¹⁰

The patient complains of a deep-seated pain and swelling due to the ongoing inflammatory edema and spread of infection in the bone. The associated teeth are tender to percussion and may be loose. There may be regional lymphadenitis and alteration of sensation of the lower lip due to the involvement of the inferior alveolar nerve and pressure from the inflammatory process. The acute inflammatory reaction involving fluid exudate into the medulla of the mandible causes this pressure effect on the nerve and

may also cause thrombosis of vessels leading to necrosis and sequestrum (dead bone) formation.

Depending on the signs and symptoms, osteomyelitis can be classified into acute, subacute, and chronic forms. Radiographic changes do not appear immediately in the acute suppurative form of osteomyelitis as it may take about 2 weeks for the trabecular pattern of bone to change and areas of radiolucency to start to appear, usually accompanied by a periostitis. If the acute osteomyelitis is not treated effectively this will lead to chronic suppurative osteomyelitis. The infection may be a manifestation of lowered patient resistance; this sometimes occurs in immunosuppressed patients on medication or those suffering from an impaired immune defense, as in acute leukemia, human immunodeficiency virus (HIV) infection, poorly controlled diabetes mellitus or malnutrition.

Damage to the jawbones secondary to radiation, osteosclerosis or trauma may be a predisposing cause of chronic osteomyelitis. Clinically, the disease is dominated by pain and the development of intraoral and/or extraoral sinuses. Induration of soft tissues overlying the infected segments of the jawbones is marked and the distension of the periosteum with pus or inflammatory exudate which may cause trismus and difficulty swallowing. Regional lymph nodes are usually tender and enlarged. Pathological fracture may develop if the inferior border of the mandible is damaged by the infection process. The radiographic picture of chronic osteomyelitis is loss of detail of the trabecular pattern of the osseous architecture giving the bone a mottled or moth-eaten appearance (Fig 7.13). The ischemic or necrotic islands of bone tend to sequestrate, appearing more radiopaque than the surrounding bone and these form a sequestrum of necrotic bone. In younger persons subperiosteal new bone formation appears adjacent to the diseased area. This new bone, known as involucrum, tends to be structureless or granular in appearance radiographically and may surround the necrotic sequestrum and pus lying within the bone.

Management of osteomyelitis involves:

1. Culture and sensitivity testing to provide specific antibiotic therapy which generally tends to be given intravenously and for a prolonged period (several weeks).
2. Drainage and debridement, including sequestrectomy.

Fig. 7.13 Radiograph of osteomyelitis.

3. Removal of source of infection and, if necessary, decortication of the mandible.
4. Possible resection and reconstruction of the affected bone after infection is controlled.

Chronic sclerosing non-suppurative osteomyelitis (Garré's osteomyelitis)

This is a chronic form of osteomyelitis with characteristic deposition of bone, subperiosteally and endoperiosteally, in response to an inflammatory process often initiated by a dental infection of low virulence. It affects the mandible in young individuals. Clinically, the condition has the appearance of a nodular, firm swelling related to the inferior border of the mandible. The florid proliferative periostitis is characteristic of this condition in addition to the multilayers of bone formation giving the "onion skin"-like appearance radiographically (Fig. 7.14). Computed tomography (CT) scanning may help to identify the cause of infection but normally there is no sequestration of the expanded bone.

This condition may persist over a long period of time. A corticotomy and exploration of the damaged bone may be helpful. Appropriate antimicrobial therapy is required to deal with the infection. However, relapse is common. The bone gradually remodels over 6–12 months. A focus of infection is rarely identified. The condition tends to slowly resolve as patients reach adulthood but may require lengthy steroid therapy which downregulates the inflammatory process.

Diffuse sclerosing osteomyelitis of the mandible

This is an inflammatory disease of the mandible whose cause and pathogenesis is still largely unknown. The disease can occur at any age but rarely in young children and often lasts for years with recurrent pain and swelling. The radiographic appearance is variable with areas of diffuse rarefaction and some sclerosis (Fig. 7.15). Organisms cannot usually be cultured from the lesion, although it has been claimed that with meticulous culturing techniques, organisms, including *Actinomyces* species and *Eikenella corrodens*, can be recovered.¹¹ However, many believe

Fig. 7.14 Panoramic radiograph showing subperiosteal bone formation in Garré's osteomyelitis.

Fig. 7.15 Clinical picture of bisphosphonate-related necrosis of the mandible.

that the disease may be due to an autoimmune process. Various therapies have been suggested including antibiotics, anti-inflammatories, corticosteroids, hyperbaric oxygen, and intravenous bisphosphonate therapy. Only partial success has been claimed, and surgical treatment may be necessary, consisting of either debridement of the lesion or decortication, or even resection of the mandible.¹² Recurrence often occurs, though ultimately the condition often burns itself out leaving a dense sclerotic mandible.

Osteoradionecrosis

This is a type of bone necrosis which occurs following radiotherapy to the jaw region and often becomes secondarily infected.¹³ Radiotherapy induces endarteritis obliterans which reduces vascularity and renders the bone vulnerable to infection. Once secondary infection develops it spreads through the bone but sequestration is delayed in these cases. Patients who have had radiotherapy are potentially at risk of developing this type of osteomyelitis and the mandible is particularly at risk if it has received more than 55 Gy of radiation. Extraction and other surgical procedures should be carried out as atraumatically as possible. Primary closure of the socket and pre- and postoperative antibiotic treatment, antiseptic mouthwash and good oral hygiene are essential. The use of hyperbaric oxygen to increase the blood supply of the affected bone has proven successful in the management of these cases as have other new and experimental treatments.¹⁴ Better collimation of the beam of radiation and protection of tissues adjacent to tumors have reduced, although not eliminated, this unpleasant sequel.

Osteonecrosis secondary to bisphosphonate therapy

Bisphosphonates reduce pain and bone destruction due to metastatic disease, particularly in patients with multiple myeloma, breast and prostate carcinoma. The medication inhibits bone resorption by reducing osteoclastic activity.¹⁵ Long-term administration of high-dose intravenous bisphosphonates may lead to osteonecrosis of the jawbones. This is

Fig. 7.16 Bisphosphonate-related osteonecrosis of the jaws (BRONJ), maxillary tuberosity region.

mainly due to a reduction of the vascularity, which together with inhibition of osteoclastic activity, reduces bone turnover. Both are required to protect the bone from the risk of necrosis and superadded infection. There is a lesser risk of this condition occurring in patients taking oral bisphosphonates to prevent osteoporosis.

The mandible is most often affected and the disease usually arises after dental treatment (Fig. 7.16). The patient may present with either a non-healing extraction socket or exposed bone which does not respond to conservative management and antibiotic therapy. Extraction of infected or periodontally involved teeth should be carried out before the administration of bisphosphonates, if at all possible. Surgery should be avoided whenever possible. It has been suggested that the assessment of the bone's reparative ability can be assessed by measuring the terminal polypeptide chain (CTX).¹⁶ Perioperative and postoperative antibiotics are essential for extractions. Chlorhexidine mouthrinse pre- and postextraction are also considered valuable. In non-urgent cases the risk may be reduced if the bisphosphonate is withheld for 3 months prior to surgery. This must, however, be done only in consultation with the physician prescribing the drug.

Cavernous sinus thrombosis

Thrombosis of the cavernous sinus is an extremely serious condition which may occur secondary to an acute infectious process of the dental, nasal, and orbital regions. The cavernous sinus is a fold between the inner and the outer layer of dura matter. It is lined by endothelial cells and drains venous blood from the brain. Each sinus extends from the superior orbital fissure anteriorly, through the apex of the petrous part of the temporal bone posteriorly. There are two general mechanisms by which infection may reach the cavernous sinus through the venous network of the dentofacial region. The first is the facial, or afferent system, which comprises the facial vein which communicates with the superior ophthalmic veins,

since these veins are in direct communication with the cavernous sinus through the superior orbital fissure. The second mechanism is the pterygoid venous plexus, or the efferent system. Infection may reach the pterygoid venous plexus in a retrograde fashion through the posterior facial vein or the internal maxillary vein. Infection from the pterygoid venous plexus would reach the cavernous sinus via the inferior ophthalmic vein or the veins of the foramen ovale and lacerum (Fig. 7.17).

The signs and symptoms of cavernous sinus thrombosis are those related to venous obstruction, and involvement of the nerves within the vicinity of the cavernous sinus (the oculomotor nerve, trochlear nerve, and the ophthalmic and maxillary divisions of the trigeminal nerve). Edema of the retina, eyelids and bridge of the nose, as well as ocular swelling are the main characteristics of cavernous sinus thrombosis. This is due to distension of the tissues behind the eyeball. Involvement of the cranial nerves in the septic condition causes ptosis of the upper eyelid, dilatation of the pupil of the eye, and restriction of eye movement. In addition, the patient may show symptoms of septic shock which includes pyrexia, profuse sweating, vomiting, and coma. Treatment of this condition should be prompt. The patient should be admitted to hospital, the airway should be maintained, and fluids should be administered. Antibiotics should be administered immediately and adequately. Anticoagulant therapies are used to prevent extension of the thrombus and interference with the venous drainage of the brain. Drainage of pus should be carried out as soon as possible. Permanent cranial nerve damage, brain damage, and death have been reported following a septic cavernous sinus thrombosis of dental origin.

Fig. 7.17 Axial CT scan showing cavernous sinus thrombosis (arrowed).

Necrotizing fasciitis

This is a rapid spreading infection of the skin causing necrosis of the subcutaneous tissue.¹⁷ A combination of aerobic and anaerobic microorganisms is responsible for this condition which occurs most often in immunocompromised patients. A dental source of infection is rare but possible (Fig. 7.18).

Clinically, there is loss of skin due to the necrosis of the underlying subcutaneous tissue. Other areas of the skin may appear erythematous, edematous, rapidly changing to purplish and black in color. The patient requires aggressive and immediate surgical intervention.¹⁸ The necrotic tissue requires wide excision to healthy margins. Intravenous fluid support is given together with a combination of clindamycin, penicillin, and metronidazole until alternative therapy is chosen following culture and sensitivity. Death has been reported from this condition.

Actinomycosis

This is a chronic suppurative granulomatous infective process which is characterized by the development of swelling in the region of the face and neck. It is normally a soft tissue infection but can occasionally involve bone. The causative microorganism is *Actinomyces israelii* which is present in the normal oral flora.

Damage to the tissue, resulting from either lower tooth extractions or jaw fractures, creates a condition of low oxygen tension in which the organism becomes invasive. The condition starts as a swelling, which may occur up to several weeks after the trauma, usually within the submandibular region. The swelling appears first as a firm and indurated lesion and the overlying skin is usually inflamed, firm but may have a bluish color. Within the swelling multiple abscesses may form with sinuses draining fluid containing yellow granules (sulfur granules) which appear microscopically as a mass of Gram-positive mycelia and polymorphs (Fig. 7.19). Radiographic examination may reveal little destruction of affected bone as the

Fig. 7.18 Necrotizing fasciitis of the submandibular region.

Fig. 7.19 Mandibular actinomycosis showing (a) a raised firm and inflamed swelling and (b) sulfur granules in the resected specimen.

infection is essentially one of the soft tissue. Penicillin is the drug of choice in addition to adequate incision and drainage. The organism is penicillin-sensitive but it takes time for the antibiotic to penetrate the granulomatous reaction of the body. Antibiotic treatment must be continued for at least 6 weeks. Surgical removal of any infection will facilitate the recovery.

***Mycobacterium* infection of the oral mucosa and jawbones**

This is a specific granulomatous condition which is caused by *Mycobacterium tuberculosis*. This condition is rare but tends to be more common in developing countries. The tongue is the organ most commonly affected by this condition (Fig. 7.20). The lesion may be primary (often from infected milk) usually presenting as enlarged nodes in the neck, or can be secondary to pulmonary tuberculosis (when the causative organism is coughed up in infected sputum). *Mycobacterium tuberculosis* is present in the sputum and gains access to the deeper parts of the oral mucosa as the result of minor trauma following dental extractions or due to abrasion of the mucous mem-

brane. The invading microorganism may also gain access to the jawbones and cause a tuberculosis osteomyelitis. Clinically, the affected lesion will be a swelling with multiple draining sinuses. Looseness of the teeth and sequestration of the affected bone may be clinically apparent. With new subperiosteal bone formation, an involucrum is rarely observed. Enlargement of the submandibular and cervical lymph nodes (a condition known as scrofula), which are rubbery in consistency, with erythematous overlying skin, is a characteristic of infection with *Mycobacterium bovis*; in time an extraoral sinus develops.

Histological examination shows caseation (a “cheesy” form of necrosis) in the centre of the granuloma. The presence of tuberculous bacilli in the specimen, appearance of the primary focus in the chest radiograph, and a biopsy of the lesion will confirm the diagnosis. Management of this case will include medical treatment and surgical intervention. Isonicotinic acid hydrazide (INH), para-aminosalicylic acid (PAS), and rifampicin are still the drugs of choice. Incision and drainage of the localized abscess and sequestrectomy of dead bone are indicated. In addition, extraction of the affected teeth and

Fig. 7.20 Tuberculosis of the tongue. The lesion in this case is secondary to pulmonary TB and coughing up infected sputum.

Fig. 7.21 Photos of (a) primary chancre, (b) secondary snail track ulcers of the soft palate, and (c) tertiary gumma of the palate. The chancre and snail track ulcers are highly infectious.

the surgical excision of the involved cervical lymph nodes may be recommended.

Syphilis

This is a chronic infectious disease which is caused by the spirochete *Treponema pallidum*. Though now rare, primary (the chancre), secondary (skin rashes, lymphadenopathy, mucous patches, and snail track ulcers), and tertiary (gumma or syphilitic leukoplakia) may be found in the oral cavity (Fig. 7.21). The first and second stages are highly infectious. Bony changes may occur in the tertiary stage of syphilis. The periosteum is a common site for the development of gumma, with the midline of the palate being classically involved leading in time to oronasal fistula. This appears radiographically as peeling of the periosteum away from the underlying bone and the formation of sclerotic bony margins at the periphery. Gumma may extend to the underlying bone and cause syphilitic osteomyelitis. The condition is diagnosed by the identification of the *Treponema pallidum* using dark field microscopy, serological tests, and biopsy of the granulomatous tissue. Long-term penicillin is the drug of choice in addition to local measures to deal with damaged soft tissue, sequestered bone, and involved teeth. The fourth stage of syphilis is rare; it affects the cardiovascular system causing aortic aneurysms or aortic valve incompetence. The central nervous system may be involved which may lead to dementia or spinal cord disease.

Congenital syphilis is rare because treatment during pregnancy eradicates the infection. The characteristic features of an infected baby include saddle-nose deformity, tapering widely separated incisors (Hutchinson's teeth), domed-shaped molars (Moon's or mulberry molars), and papules at the angle of the mouth which heal forming radiating scars (rhagades).

Chapter 8

Armamentarium for Basic Procedures

Ala Al-Musawi

This chapter will deal with the basic instrumentation required for both soft tissue and hard tissue oral and maxillofacial surgery procedures. As well as basic instrumentation, it will include dental forceps and dental elevators, the rationale and choice of suture materials, and current instrument sterilization techniques. It will also discuss new innovations in surgical instruments.

Basic instrumentation for soft tissue procedures

Basic soft tissue instrumentation consists of a scalpel for making incisions (Fig. 8.1), toothed and non-toothed forceps (Figs 8.2–8.4) for grasping tissues and arresting bleeding vessels, Allis-type clamps (Fig. 8.5) for appropriately holding biopsy specimens and tissue margins, retractors (Figs 8.6, 8.7), as well as a range of forceps ranging from smaller mosquito-type forceps to larger Kelly and Schmidt-type forceps (Fig. 8.8), needle-holding forceps (Fig. 8.9), and appropriate scissors (Figs 8.10–8.12). All of these instruments can be combined to make an appropriate soft tissue instrument tray.

Fig. 8.11 Iris scissors.

Fig. 8.12 Metzenbaum scissors.

Basic hard tissue instrumentation

For surgery involving the mandible or maxilla, the basic soft tissue instrumentation is required, and additionally, one requires periosteal elevators (Figs 8.13, 8.14) to raise periosteum from bone, periosteal retractors (Figs 8.6, 8.15), curettes (Fig. 8.16) and rongeurs (Fig. 8.17) for removing and scraping bone, and bone files (Fig. 8.18) for smoothing the bone.

Fig. 8.15 Langenbeck retractor.

Fig. 8.16 Curettes.

Fig. 8.17 Rongeurs.

Fig. 8.18 Bone files.

Drills

An appropriate drill for removing bone (Fig. 8.19) will be either gas-powered or electric-powered and will not exhaust gas or air through the tip of the handpiece, since this gas can force debris and bacteria into the bone and can even cause an air embolus. Any gas used to power the drill should exhaust back along the tubing into the operatory or into a scavenging device. For preference, drills should have an automatic irrigation system built into them which is linked to the drill control and can be used in conjunction with a sterile irrigant solution. Burs should be appropriate bone-cutting burs rather than burs intended to cut enamel and dentin.

Fig. 8.19 Surgical drill.

Dental elevators

Elevators are often used in conjunction with dental forceps to remove teeth and roots.¹⁻⁴ The general principle in the use of the elevators is that the surrounding alveolar bone is used as a fulcrum for the action of the elevator rather than the adjacent tooth, unless it is intended to also remove the adjacent tooth. If the alveolar bone is used as a fulcrum and it is crushed by the elevator, this bone should be removed with a curette or bone file. Elevators that have a right-angle point of elevation can exert significantly higher forces on the mandible than those with an in-line direction of elevation. Care should be taken with such instruments (e.g. Cryer's elevators) since fracture of the mandible is possible if these instruments are used inappropriately. Similarly, instruments with a so-called T-bar handle can exert even more force on the mandible, and particular care should be used with these instruments (e.g. Winter's elevators). Examples of dental elevators are illustrated in Figs 8.20–8.27.

Dental forceps

Dental forceps have remained largely unchanged since they were introduced by Charles Tomes in the 1800s. Prior to this, instruments such as the dental key and pelican were employed. Dental forceps essentially come in two types. The first is the in-line forceps where the handle of the forceps is in line with the dental arch. To a certain extent, these forceps are safer but rely on the inherent strength in the surgeon's wrist. A particular example of an in-line forceps is the cowhorn forceps which is meant to be placed between the bifurcation of the roots of a lower molar and will either remove the molar intact or will split the molar through the bifurcation enabling both sections to be removed separately.

The second type of forceps is the so-called Ash forceps (because they were marketed through Claudius Ash and Sons, dental supply house), and these are forceps that have a handle that comes out at right angles to the arch. Potentially, these forceps can create much greater force on the tooth, through the principle of levers. It is possible to fracture the mandible with these instruments, so care must be taken. There are different Ash forceps for lower molars, premolars, and incisors. Many dentists, however, prefer to use premolar forceps for the molars, grasping the mesial root only so that either the whole tooth will be removed, or if it splits, the mesial root will be removed making the distal root easier to remove on its own. Although Ash-type forceps are sometimes used for maxillary teeth, they are usually reserved for mandibular teeth, and maxillary teeth are removed with in-line forceps. These can be specifically for the left and right maxillary molars and then separate ones for the premolars and straight forceps for the upper canines and incisors. Illustrations of appropriate instrumentation are shown in Figs 8.28–8.34.

Fig. 8.34 Ash lower premolar incisor and canine forceps.

Ancillary instrumentation

In addition to the instrumentation already shown, additional instrumentation required for most surgical procedures includes:

1. Suction, which is normally electric or vacuum driven, and suitable suction tips that work well intraorally are illustrated in Figs 8.35 and 8.36.
2. Cautery, diathermy, or electrosurgical instrumentation is often required for surgical procedures for both cutting and coagulation. There are technical differences between these systems. In a monopolar diathermy system (Fig. 8.37) there is a small active electrode and a large indifferent electrode, which takes the form of plate in contact with the body. The small active electrode is the diathermy tip but its effect is not localized as it spreads towards the indifferent electrode. By altering the waveform the tip can predominately cut or coagulate. In a bipo-

Fig. 8.35 Yankauer suction tip.

Fig. 8.36 Surgical suction tip.

lar system (Fig. 8.38) both tips of a pair of forceps are insulated from each other and form the two electrodes. The current and tissue damage is localized to the tissue between the forceps tips and does not spread and there is no large indifferent electrode in another part of the body. Because of this there is no current passing through the rest of the body so it is safe for patients with pacemakers etc. Desiccation is a cauterizing process whereby a single wire has an area of high resistance so it can become hot at that point and cauterize. Desiccation instruments tend to be of lower power and energy levels and are often disposable (Fig. 8.39).

3. Bone wax (Fig. 8.40) is also often used when bleeding is encountered during intraosseous surgery. It can be squeezed into the cancellous spaces of the bone and will cause hemostasis. Bone wax is ilable which are resorbable. In a dental socket where bleeding is a problem, one normally uses a material such as Surgicel® (Fig. 8.41) or Gelfoam® (Fig. 8.42).

Fig. 8.38 The insulated tips of a bipolar diathermy system. Each tip is a separate electrode.

Fig. 8.39 A disposable low-power cautery unit.

Sterilization of instruments

Many instruments used today are disposable single-use instruments, and no attempt should ever be made to reuse these instruments. In theory, the more single-use instruments are used, the better the chain of sterility.

Fig. 8.40 Bone wax.

Fig. 8.41 Surgicel®.

Fig. 8.42 Gelfoam®.

Fig. 8.43 Steam autoclave.

For instruments that are not single use and must be reused, they must be sterilized between surgical procedures. This involves removal of all organic and inorganic debris from the instrument, and this can be done manually but is better performed by ultrasonic cleaning. Following ultrasonic cleaning, the instruments should be packaged in appropriate bags and sterilized. For most instruments, autoclaving to a temperature of 134°C for 3 minutes, or 121°C for 15 minutes will sterilize instruments of all known bacteria and viruses (Fig. 8.43). To be effective, however, the steam must penetrate through to the instruments, and the package must not be blocked by other packages that prevent the full effects of the steam to be effective.

For more delicate instruments, ethylene oxide can be used for sterilization, but this is not universally available and usually takes up to 24 hours for instruments to be available following ethylene oxide sterilization, since time must be allowed for the ethylene oxide to disperse following appropriate sterilization.

Radiation is used to sterilize some instruments, but more often, it is used to sterilize alloplastic grafts including bone grafts. Bone grafts sterilized by radiation may maintain more activity than those sterilized by ethylene oxide.

Lower-temperature autoclaves that are combined with formaldehyde are available and do ensure sterilization at a lower temperature for some instruments.

There is no known reliable method of removing or sterilizing prions from surgical instruments, and in the present state of knowledge, if one is operating on a patient with known or suspected prion disease, all instruments must be appropriately disposed of following the procedure, and no effort must be made to reuse the instruments. Most authorities have regulations in place for how and where to perform surgery in a patient with suspected prion disease.

Suture materials and needles

Suture materials can be classified in a number of different ways (Fig. 8.44).

Resorbable and non-resorbable

Resorbable sutures include catgut in its various forms, polyglycolic acid (Dexon®), polyglycolide-lactide

Fig. 8.44 Sutures: fast resorbing gut; regular gut; chromic gut; polyglycolic acid (Dexon®) in different forms; polyglycolide-lactide (Vicryl®) in different forms; polyglactin irradiated (Vicryl Rapide®); polyglactin solid (Monocryl®); polydioxanone (PDS®) in different forms; polyglyconate (Maxon®) in different forms; silk; nylon; polypropylene (Prolene®).

(Vicryl®), polydioxanone (PDS®), and polyglyconate (Maxon®). Resorbable sutures are essentially classified as fast resorbing, medium resorbing, and long resorbing. The fast-resorbing sutures include catgut where fast-resorbing gut resorbs in 2–3 days, regular catgut resorbs in 5–7 days, and chromic catgut resorbs in 10–14 days. Intermediate-resorbing materials include polyglycolic acid and polyglycolide-lactide, whose resorption time is 4–6 weeks when used intraorally. The solid form of polyglycolic acid, which is marketed as Monocryl, also resorbs in 4–6 weeks. By irradiating polyglycolic acid, a faster-resorbing version is available which resorbs in 14–21 days and is marketed as Vicryl Rapide®. Long-resorbing sutures include polydioxanone and polyglyconate. Intraorally, these resorb in around 120 days, although they start to lose their strength after about 40 days. Non-resorbable sutures include silk, nylon, polypropylene (Prolene®), cotton, and Gore-Tex®.

Braided and solid

Braided sutures consist of multiple filaments woven together. The advantage of a braided suture is that it is easy to handle and easy to knot, but disadvantages include the fact that they tend to leave more prominent stitch marks on the skin and can lead to “wick-ing” where fluids (possibly containing bacteria) can be attracted to the suture by capillary action. A solid suture consists of a solid tube of the suture material which means it will have memory and be harder to handle and harder to knot, but will leave less prominent stitch marks and will not have a tendency to “wick”. Braided sutures include silk, cotton, and Gore-Tex® as well as the synthetic materials polyglycolic acid, polyglycolide-lactide, polydioxanone, and polyglyconate. Solid sutures include catgut, nylon, polypropylene, and the synthetic materials polyglycolic acid, polyglycolide-lactide, and polydioxanone and polyglyconate, which can be manufactured in either variety.

Naturally occurring materials or synthetic

Naturally occurring materials include silk and cotton as well as catgut. Since catgut is a biological product derived from the intestines of sheep, concern has been raised about the possibility of transmission of prion disease via catgut sutures, and at the present time, this remains theoretical but debatable. Catgut sutures normally resorb in 5–7 days, but by treating the catgut with chromic acid (chromic gut), its handling properties can be improved, its tissue irritability can be decreased, and its resorption time increased to 10–14 days. If, however, catgut is irradiated, it will resorb more rapidly and is commercially available as “fast-resorbing gut”. This will resorb in 2–3 days and is useful for sutures around the eyelids. Catgut is resorbed by enzymatic action, and this will cause some tissue irritation, which is often seen around catgut sutures.

Synthetic sutures are usually resorbed by oxidation or hydrolysis, causing less tissue reaction. Examples of synthetic resorbable materials include polyglycolic acid, polyglycolide–lactide, polydioxanone, and polyglyconate. These synthetic materials are generally produced by extrusion and, therefore, can be made in many different configurations. They can usually be manufactured in almost any color, and even in a candy stripe design, and many manufacturers do offer a choice of colors. They can be manufactured as either braided or solid configurations, and also as a combination whereby a braided suture is then coated with a thin layer of the liquid material; this produces essentially a braided suture with a smooth outer layer, which has the handling advantages of a braided material with the lack of irritability of a solid material and also the lack of ability of the tendency to “wick”. These are properties that cannot be matched by natural materials. However, the synthetic materials do tend to be more expensive than natural materials.

Uses for the various suture materials

In general, one likes to use a resorbable material in the mouth so that sutures do not need to be removed. Since only single-layer suturing is normally appro-

priate intraorally, this is normally with a 3-0 or 4-0 thickness material, and plain catgut, chromic catgut, polyglycolic acid or polyglycolide–lactide are normally appropriate. Extraorally, tissues are often closed in layers, and as such, the appropriate material determines the layer. Fascia can normally be repaired with an intermediate resorption time material such as polyglycolic acid or polyglycolide–lactide, but chromic catgut may also be appropriate. Muscle layer requires a material that will retain its strength for 2–3 weeks, and again polyglycolic acid or polyglycolide–lactide are appropriate. For the subcutaneous tissues, a suture is required which will maintain its strength for around 14 days, and again chromic catgut, polyglycolic acid or polyglycolide–lactide are appropriate. For the skin, a 5-0 or 6-0 nylon is appropriate, or a running subcuticular suture which is normally carried out with a longer-term resorbable solid suture is appropriate. Monocryl, polydioxanone, or polyglyconate would be appropriate for this purpose.

Suture needles

Most suture materials come ready swaged to the needle. Although needles with an eye are still manufactured, and clinicians can thread their own needles, less tissue damage is caused by a ready swaged suture. Needles come in different varieties and combinations. For oral surgical use, a needle which is part of the circumference of a circle is normally used, and straight or J-shaped needles have little application. For personal preference, anything between three eighths and five eighths of a circle are appropriate, and for the many procedures in the posterior part of the mouth, a one half round or five eighths round needle is felt to be more appropriate. For extraoral suturing or suturing towards the anterior part of the mouth, a three eighths needle may be more appropriate.

Needles can be round bodied to suture delicate tissues since there is less chance of the suture cutting through the tissues, but for many oral tissues, a cutting needle is appropriate. Cutting needles are triangular in cross-section and can be forward cutting or reverse cutting depending on the way they are made (Fig. 8.45). For intraoral use, a reverse-cutting needle is often appropriate, since a forward-cutting needle

Fig. 8.45 Needle patterns. Round-bodied needle; cutting needle; reverse-cutting needle.

has a tendency to cut through the tissues as you pull it through, sometimes pulling the suture out. Combination needles are available, such as a taper cut needle which is a cutting needle for the first one third of the needle and then becomes round bodied so that as you pull it through the tissues, it does not cause further damage.

Fig. 8.46 Piezoelectric bone-removal system.

New innovations in surgical instrumentation

Although over the years many different systems have been suggested for removing bone, none has superseded the dental drill. More recently, a piezo instrument using high-frequency vibration to remove bone has been advocated (Figs 8.46, 8.47).⁵ Initially, these instruments lacked power and could only remove small areas of relatively thin bone. However, new generations of these instruments are expected to have greater power and more flexibility to change the frequency and wavelength of the vibrations to achieve a more efficient cutting action. It is claimed that the heat generated and peripheral damage produced are much less than with a dental drill, and, therefore, with further improvements, they may have a place in bone removal in oral and maxillofacial surgery.

Chapter 9

Basic Surgical Principles

M. Anthony Pogrel and Fabio Kricheldorf

This chapter covers the basic principles of aseptic technique, cutaneous and intraoral incisions, the principles of soft tissue biopsy techniques, and the principles of suturing of wounds and lacerations.

Aseptic technique

Since the late 1800s, when bacteria were first recognized, the concept in surgery has turned from accepting pathogenic agents, and hoping that the body can overcome them, to attempting to eliminate them from the surgical field. In hospitals, most operations are carried out using a truly aseptic technique. All instruments used are sterile, having been autoclaved or all organisms eliminated by some other physiochemical means. In addition, the operating room itself is surgically clean, and all trays, etc., on which instruments rest are sterile. The surgeon wears sterile gloves and a sterile gown, and a mask, head covering, and shoe covers or separate footwear that is only worn in the operating room. An aseptic technique is employed whereby sterile and non-sterile objects do not contact each other so that there is a continuous chain of sterility; the only organisms that come in contact with the patient are their own endogenous organisms. In this way, infections should not occur, and, in theory at least, antibiotics and other chemotherapeutic agents should be unnecessary if no exogenous infecting agents are introduced. In practice this type of sterility, although ideal, is imperfect. Infections do still occur in the operating room for a variety of reasons and

antibiotics do still need to be employed in many cases.

Questions have been raised over the years as to the necessity of wearing caps, masks, and shoe coverings.^{1,2} Studies have even shown that in longer procedures masks often become reservoirs of the surgeon's saliva and nasal secretions, and organisms may be demonstrated to fall from the mask to the patient. It has been suggested that for longer procedures, not wearing a mask, but also not talking, may disseminate fewer organisms.

Nevertheless, the rules for carrying out invasive surgery in the operating room environment of a hospital are fairly standard and clear cut. The rationale in a dentist's, or oral surgeon's office, is, however, less clear cut. For many years, dentistry and relatively minor oral surgical procedures were carried out in an outpatient office without the use of gloves, cap, or mask and with only a clean gown or coat. This changed in the 1980s when new generations of pathogenic organisms were identified including hepatitis B and hepatitis C viruses, and human immunodeficiency virus (HIV). Following this, to protect both the dentist and the patient, dentists started to wear gloves, caps, and masks.

At the present time, there is no standard for the level of asepsis to be practiced in a dental office or for oral surgery performed in an outpatient setting. In all cases, dentists will now wear caps, masks, and gloves, but in most cases they will continue to wear their outside shoes. Gowns are often worn but are often not sterile but rather cleaned and laundered and changed between patients. Gloves are normally sterile for invasive procedures but are generally non-sterile for non-invasive procedures. Aseptic technique is not strictly followed in most cases, and, although all instruments are sterile and are normally placed on a sterile surface, they may on occasion come in contact with non-sterile instruments and techniques. For this reason, the chain of sterility is less secure in an office environment, and thus antibiotics tend to be used more frequently, and often prophylactically.

Principles of surgical incisions

Surgical incisions are used to gain access to the area, either intraorally or extraorally, that is the object of the surgery. Other instruments such as retractors pull the tissues aside in order to visualize the tissues exposed. In general terms, incisions should be no longer than is minimally necessary, and the skin or mucosal incision should be the shortest incision with incisions in the deeper layers being longer. In this way, the skin or mucosal surface can be slid from side to side to gain maximal access to the deeper layers without the necessity of increasing the length of the surface incision.

Incisions are most often made with a surgical scalpel, and for oral and maxillofacial surgery, the #15 blade with its rounded tip is still the most popular, although the #11 blade with its pointed tip and the #12C blade with its smaller rounded tip are popular for some procedures with some surgeons. Incisions should be made with one single firm movement using the palm of the hand as a support for the scalpel handle to avoid undesirable instability.

Incisions can also be made with electrosurgery or a laser, or even combined instruments such as a scalpel blade with electrosurgery capacity built into it, although these latter instruments are often expensive, somewhat unreliable, and not widely used. Electrosurgical cutting, although it produces a relatively bloodless field, does so at the expense of surface cauterization and does produce more wound breakdown, scarring and wound contracture, and so is generally not employed in esthetic areas.

Skin incisions around the face are best sited either in established skin creases, the site of future skin creases (in young patients), or in the relaxed skin tension lines (RSTL) (Fig. 9.1).³ These lines generally run at right angles to the direction of the underlying musculature and are roughly equivalent to the original lines described by Langer in 1861,^{4,5} which he produced by puncturing the skin of fresh cadavers with

Fig. 9.1 The relaxed skin tension lines of the face which are the sites of choice for surgical incisions. In general, they run at right angles to the underlying muscles.

a dagger. He then observed how much the incision gaped compared with the site of the wound. From this he drew lines over the face where wounds do not tend to gape. These lines really represent a function of skin extensibility and reflect the way the skin was stretched by the dagger as it entered the tissues. Although there are differences between these and the relaxed skin tension lines, or the so-called lines of minimal tension of Converse,⁶ they all follow the same general principles. Differences do occur on the face since the original Langer's lines sometimes cross the natural crease lines at right angles. If incisions are placed in this way, they will produce minimal scarring and the best esthetic results. One also needs to be cognizant of any underlying nerves, particularly the branches of the facial nerve. Incisions made on the oral mucosa are generally full thickness over the mandible and maxilla and go down to bone.

Types of intraoral incisions

1. The straight vertical incision is shown in Fig. 9.2, and produces the most esthetic result with minimal scarring. It is indicated for obtaining access to deeper lesions, for tunneling procedures, and for many minimally invasive intraoral procedures. Access, however, is limited.
2. The straight horizontal incision in the buccal sulcus as shown in Fig. 9.3 is often indicated for management of periapical pathology, impacted teeth, tumors, and sinus procedures. It does, however, tend to produce more scarring than a vertical incision.
3. The intrapapillary incision, sulcular incision, or gingival margin incision is carried out using a scalpel at a reverse bevel and sectioning the interdental papillae and some of the supracrestal and transeptal fibers of the periodontal ligament. It is shown in Fig. 9.4 and gives excellent access with minimal scarring and can be used buccally, palatally, and lingually. However, there can be problems around crowns and bridges and it can cause gingival recession, root exposure, and occasionally subsequent gingival problems.

Fig. 9.2 A straight vertical incision intraorally for access to a variety of soft tissue and bone lesions.

4. The gingival margin incision can be combined with a releasing incision at an angle of about 70° to allow improved access to a bony lesion but maintain adequate vascularization of the flap (Fig. 9.5). This is a popular incision, but one disadvantage is that if the releasing incision is made anteriorly, the appearance of the papilla that is included in the releasing incision may become atypical, and the vertical scar produced may be visible on people with smile lines in the esthetic zone which expose the gingiva.
5. A releasing incision can be made at each end of a gingival margin incision. The releasing incision should be divergent to protect the vascularity of the flap, particularly in its distal regions, and the further back the releasing incisions are made in the

Fig. 9.3 A horizontal sulcular incision suitable for access to periapical pathology and sinus procedures.

Fig. 9.4 An intrapapillary or sulcular incision used to give access to the palatal surface of the alveolus.

Fig. 9.5 A gingival margin incision incorporating a releasing incision which is wider at its base than its apex to protect the vascularity of the flap (arrows). If the releasing incision is in the esthetic zone of the mouth, the esthetics may be compromised.

oral cavity, the less they will be visible when the patient smiles (Fig. 9.6). It is a general rule of all soft tissue flaps that the base should be wider than the apex to protect the vascularity.

6. Incisions for third molars are generally a Winter-type incision, which comes down the external oblique ridge to the disto-buccal line angle of the second molar and then continues around the gingival margin of the first and second molar, occasionally with a releasing incision anteriorly if necessary (Fig. 9.7). This gives good access but it can be difficult to suture the papillae and can cause gingival recession on occasions. An alternative incision for third molars runs down the external oblique ridge to the disto-buccal line angle of the second molar and then proceeds as a releasing incision down into the sulcus terminating around the posterior edge of the first molar so as not to encounter a small arteriole which is often present opposite the first molar (Fig. 9.8).

Fig. 9.6 A releasing incision at each end of a gingival margin incision gives excellent access with the base wider than the apex to protect the vascularity.

Fig. 9.7 The Winter-type incision for access to a third molar. An anterior releasing incision can be made if necessary.

Fig. 9.8 An alternative third molar incision which does not involve access to the gingival sulcus of adjacent teeth.

Fig. 9.9 The double Y-type incision which gives excellent access for a palatal torus or similar lesion.

7. For lesions such as a palatal torus, a double Y-type incision down to bone is often indicated. This incision leaves a good blood supply for the palatal mucosa and allows excellent access to the torus which can then be removed with a combination of drills and chisels (Fig. 9.9).

Following the initial incision, if the deeper soft tissues are to be incised, this can be done with either a sharp or a blunt technique. A sharp technique will employ a scalpel or dissecting scissors and involves a thorough knowledge of the anatomy of the area to avoid damaging important structures. In some cases, a #15 scalpel blade laid on its side and used in a scraping motion can be a compromise method of quickly going through tissue layers but leaving adequate opportunity to visualize important structures. With a blunt technique, a pair of mosquito, or similar, forceps is placed in the tissue layer closed, is then opened, and then withdrawn and closed outside the body. In this way, an incision is gradually widened (with sharp dissection or excision of structures where necessary) without damaging or crushing structures. The mosquito forceps should not be closed within a cavity since important structures may be trapped between the blades.

When access is being gained to the bone of the mandible or maxilla, periosteal elevators will need to be employed to gain access to the bone itself. Periosteum should be retracted with care with a periosteal elevator, bearing in mind that as the subject ages a greater proportion of the blood supply to the bone comes from the periosteum, particularly in the mandible, and, therefore, it should be preserved wherever possible.

Principles of soft tissue biopsy

A biopsy entails obtaining material suitable for establishing a tissue diagnosis. In principle, a biopsy can be either incisional, where a representative portion of a lesion is removed for examination, or it can be excisional, where the whole lesion is removed.

Biopsy can be performed with a scalpel, electro-surgery, laser (Fig. 9.10), tissue punch (Fig. 9.11), or a combination. A scalpel is most frequently employed, and once a portion of the lesion has been excised, care must be taken when handling the tissue so as not to crush or distort the tissue. This means that forceps must be used judiciously in securing the specimen. The use of a scalpel, however, does enable the soft tissue to be sutured back with minimal distortion. If a tissue punch is used, there is usually less distortion of the specimen, but since the punch is circular, a round defect is produced which is more difficult to close and often has to be left open to granulate. Nevertheless, a tissue punch, either 3 mm or 5 mm in diameter, is an excellent way to obtain a palatal biopsy since the punch can be taken down to palatal bone with ease to obtain a full-thickness specimen.⁷ In most cases, the punch is used to sever the lesion laterally from the surrounding tissue and a pair of forceps is then used

Fig. 9.10 A surgical carbon dioxide laser which can be used for soft tissue surgery, but in practice has limited use and has not replaced the surgical scalpel. Courtesy of Luxar.

Fig. 9.11 A dermatological tissue punch which can be very useful for obtaining deep biopsy specimens, particularly from the palate where the punch can be inserted down to palatal bone.

Fig. 9.12 The longitudinal incision for removal of a lip lesion.

to retract on the specimen which can be dissected from the underlying bed with scissors or periosteal elevator as appropriate. Although electrosurgery or laser can be used to obtain a biopsy specimen for pathological examination, this is generally not preferred since the electrosurgery or laser will both cause coagulation or vaporization damage to the bed of the tissue which makes examination of the margins more difficult and problematic.

Biopsy of the mucosal surface of the lip

Excisional biopsy of lesions such as irritation fibromas, mucus retention cysts, and other minor pathology of the lips is common. Although these are often viewed as very straightforward lesions to remove, there is morbidity associated with them since the lips are such sensitive and minutely controlled organs. Most of the lesions occur on the lower lip since it is

much more often traumatized than the upper lip. If the lesion is removed via a longitudinal incision, this produces the least scarring but can interfere with the small branches of either the facial nerve or the mental nerve in the lips. It is sometimes surprising how often excision of a small mucocele can leave the patient with either a slight weakness of part of that area of the lower lip or a small area of paresthesia due to interference with minor nerve branches. Interference with the 7th nerve is usually not a problem in normal movements but only becomes apparent when a tighter lip seal is required such as blowing a musical instrument or blowing against closed lips when some escape of air will be noted. These problems become more frequent the closer one is to the commissure.

In order to minimize the risk of this occurring, incisions should be made through the mucosa only and any further tissue removal should be by blunt dissection to cause minimal trauma to any nerve branches (Fig. 9.12).

them are some proportion of the circumference of the circle), but some come in other shapes such as a J shape. A round-bodied needle is non-cutting and is generally used on friable internal organs. A cutting needle is triangular in cross-section with one edge sharpened to cut through the tissues. A cutting needle is necessary for mucosa and skin and also some of the fascial layers of the head and neck.

If the needle is bent so that the cutting edge is on the inside of the circle, it is called a forward-cutting needle since it cuts on its inside edge; whereas, if it is bent so that the cutting edge is on the outside of the circle, it is called a reverse-cutting needle since it cuts away from the direction the needle is passed. In most oral surgical procedures, the reverse-cutting needle is preferred, since a cutting needle will cut through the tissues too often (Fig. 9.14).

Today, many needles combine the best of all properties with a reverse-cutting tip and then a round-bodied needle so that the reverse-cutting portion makes the initial incision into the tissues, and then the round-bodied portion of the needle passes through the tissues without causing any further damage. These combined needles go by a number of different names such as taper cut.

Suturing techniques

Once the suture has been passed through the tissues, it must be tied in a knot. Knots can be tied with an instrument or with the hands, but in each case, the principle is the same. In general, a monofilament suture will require more knots than a braided suture since it is more likely to become untied. In most cases, the knot needs to start with a double overhand or double thumb knot, which is essentially a simple thumb knot with an extra twist on it, so that it is less likely to “give” or “slip” (Fig. 9.15). One more thumb

Fig. 9.14 The contours of (a) a forward-cutting and (b) a reverse-cutting needle. The reverse-cutting needle is usually more applicable in the oral cavity since it will not cut through the tissues.

Fig. 9.15 A double overhand, or double thumb knot.

knot is then thrown, and if this is in the same direction as the first knot, it will form a surgeon's knot which will not “give”, but if it is thrown in the opposite direction, it will form a granny knot which can loosen or be tightened (Fig. 9.16). This can be an advantage on occasions when one wishes to adjust a knot to exactly the right position and tension. However, the final knot that is thrown must convert the previous knot to a reef or square knot so that when it is tightened the knot will not loosen. Thus, there are variations in the technique, but in all cases, the first knot thrown must be able to hold the tissues in position whilst the second knot may be a square knot if the position of the first knot is ideal or can be a granny knot if further tension is required, but the final knot must convert the next-to-final knot to a reef or square knot.

As far as suturing techniques are concerned, the most frequent sutures used are simple interrupted sutures, and although there are no absolute rules, placing around three sutures per cm of length is a good compromise between having too many sutures and, therefore, too many stitch marks and too many possibilities of infection, versus not having enough sutures and having a widened scar. By making the base of the suture wider than the skin or mucosal puncture marks, a slightly everted wound edge is produced, which will flatten as it matures to blend with the adjacent skin or mucosa (Fig. 9.17).

Variations include both the horizontal and vertical mattress sutures which are generally employed intra-orally to obtain a watertight closure (Fig. 9.18). The vertical mattress suture, in particular, not only obtains a watertight closure but produces an everted suture line with a lot of tissue in contact to have the maximal chance of healing well. In particular, vertical mattress

(b)

Fig. 9.18 (a) Horizontal mattress suture. (b) Vertical mattress suture. The horizontal mattress suture will provide a watertight seal, while the vertical mattress suture will provide excellent wound apposition with the best possibility of healing, particularly in a site where healing may be compromised, e.g. over a dead space.

(a)

(b)

Fig. 9.19 (a) A locking (suitable for intraoral use) and (b) a non-locking (suitable for cutaneous use) continuous suture.

Fig. 9.20 The concept of a running subcuticular suture which is inserted in the white line of the dermis and advances by 3 mm with each pass of the needle but starts 1 mm behind the last pass needle on the opposite side of the wound. Various systems are available for starting and completing a running subcuticular suture,¹¹ but, in general, the knot is tied on the skin. Ideally, these sutures are left in place for at least 3 weeks to ensure the thinnest scar.

sutures can be used when suturing over a dead space such as a cyst cavity or an oroantral fistula. A horizontal mattress suture produces a watertight suture line.

Continuous sutures can be either locking or non-locking (Fig. 9.19). They are generally non-locking on the skin for added cosmesis, but in the oral cavity they can be locked for better closure and better waterproofing of the suture line. The risk with a continuous suture is that if it does break, the whole suture is rendered worthless; whereas, with separate interrupted sutures, the loss of one suture may not compromise the whole suture line.

A running subcuticular suture (Fig. 9.20) is an excellent skin closure technique providing the correct principles are adhered to. The running subcuticular suture needs to be inserted at the white line of the dermal junction, and each needle pass needs to be 2–3 mm but backing up 1 mm on the previous needle pass on the opposite side of the wound. If a non-resorbable material such as nylon is used, the suture

needs to come to the surface every 2cm to facilitate removal, but if a resorbable suture has been employed, this is not necessary. Running subcuticular sutures have the advantage that they can be left in for the optimal time for collagen strength across the suture line, which is about 3 weeks, without causing unacceptable stitch marks or infection which would occur if any type of suture was left in the skin for three weeks.^{9,10} Running subcuticular sutures can be in nylon or polypropylene, which are removed after 3 weeks, or a slow resorbing monofilament or coated multifilament suture, such as polydioxanone or polygluconate. Therefore, running subcuticular sutures¹¹ are particularly applicable in the areas of maximal cosmesis but can generally only be used with linear incisions. They are normally augmented with adhesive strips on the surface.

Chapter 10

Complications Associated with Dentoalveolar Surgery

Srinivas M. Susarla, Ryan J. Smart, and Thomas B. Dodson

This chapter's purpose is to review common complications associated with dentoalveolar procedures, primarily tooth extraction. While low risk, these procedures are routinely performed by general dentists and dental specialists. As such, the annual volume of these procedures results in a high number of actual complications. Unexpected complications from routine oral surgical procedures can lead to poor outcomes, deterioration of the patient–doctor relationship, and litigation. A clear understanding of the risks and benefits of dentoalveolar procedures on behalf of both the patient and practitioner is critical to modern dentoalveolar surgery.

Complications encountered with dentoalveolar surgery can be broadly classified into two groups: those side-effects and complications associated with any surgical procedure (pain, bleeding, swelling and infection) and complications specifically related to dentoalveolar procedures (oroantral communications, root displacement, alveolar osteitis). This chapter will review these complications, their frequencies, risk factors, diagnostic criteria, and management.

Side-effects of dentoalveolar procedures, 155

Oroantral communication, 162

Side-effects of dentoalveolar procedures

All operative procedures result in some degree of postoperative bleeding and inflammation, typically presenting as pain and swelling. As the body's natural mechanisms for wound repair and tissue regeneration are activated, a host of mediators will be concentrated in the wound area, resulting in activation of

nociceptive pathways and an increase in vascular permeability. While a detailed discussion of these processes is beyond the scope of this chapter, the well informed practitioner should have a general sense of the time course associated with these processes so as to gauge whether a patient's complaint of postoperative bleeding, pain, or swelling represents a normal response to surgical trauma or an aberrant reaction.

Bleeding

Etiology and prevalence

Postoperative bleeding is a side-effect of dentoalveolar procedures. In healthy patients, postoperative bleeding is typically minimal and self-limited by the clotting processes. The time course for clot formation is typically 6–12 hours postoperatively. Continuous active bleeding after this time period is considered to be excessive. In general, it is important to distinguish active bleeding from surgical site oozing. Patients will often complain of excessive bleeding because they have noticed blood in their saliva. Oozing should resolve within 36–72 hours postoperatively, should respond to pressure, and is generally a nuisance for the patient. In contrast, patients with an active bleed will often complain of their mouth filling with blood immediately after removing a gauze dressing or other local pressure measure.

Risk factors and prevention

Among the most important steps in the management of excessive postoperative bleeding is recognition of the at-risk patient. Numerous risk factors for bleeding have been identified in the literature. During the preoperative assessment, a detailed history should be obtained, including a history of disorders associated with coagulation, e.g. hemophilia, von Willebrand disease, use of medications such as antiplatelet agents like aspirin and clopidogrel (Plavix), vitamin K antagonists like warfarin (Coumadin), or heparin or its derivatives, e.g. enoxaparin (Lovenox) or

fondaparinux (Arixtra), an individual or family history of bleeding with surgical procedures, excessive bleeding upon loss of deciduous teeth, and, in females, a history of menorrhagia.

As the average age of oral surgical patients increases due to prolonged life, practitioners will encounter a greater number of anticoagulated patients. Appropriate adjuvant therapy, such as discontinuation of anticoagulant medications, factor infusions, or use of clot-stabilizing medications, should be considered in patients with risk factors for bleeding or known bleeding diatheses. Of note, patients taking clopidogrel, aspirin and other non-steroidal anti-inflammatory medication do not need to stop their medications prior to routine dentoalveolar procedures.¹

Patients on warfarin pose a common and special problem for the oral surgeon. The underlying medical problem, e.g. long-standing atrial fibrillation, deep vein thrombosis, prosthetic heart valve, or myocardial infarction, often prohibits discontinuing the anticoagulant. An acceptable, but uncommon, management strategy is to hospitalize the patient, discontinue the warfarin, and maintain the patient on a heparin bridge until the INR (international normalized ratio = $[PT_{(patient)}/PT_{(normal)}]^{ISI}$, where PT is prothrombin time and ISI refers to the international sensitivity index) is normal. An alternative option is to discontinue the warfarin preoperatively.

Care should be taken in considering the type of dentoalveolar surgery being performed. Many minor oral surgical procedures (such as single tooth extraction) can be done while the patient is anticoagulated, based on the coagulation profile.² In general, for patients on warfarin, a PT-INR <2.5 is generally acceptable if extraction of multiple (more than four) teeth is required. For extraction of one to three teeth, with no posterior teeth or surgical extractions, an INR of <3.0 is acceptable. Keeping this in mind for the patient who may need multiple extractions, staged visits may be most appropriate so discontinuation of the anticoagulants can be avoided.

Treatment

Excessive postoperative bleeding can be prevented intraoperatively by meticulous tissue management and local measures. In general, careful removal of granulated/infected tissue, minimal manipulation of surgical flaps to avoid tearing, use of local anesthetic with vasoconstrictor, primary wound closure, and the application of topical agents, such as absorbable gelatin sponge, oxidized regenerated cellulose fabric, or chitosan bandage, can limit most postoperative bleeding. Direct pressure with gauze in the immediate postoperative setting is an important method of limiting bleeding as the initial clot forms. Patients should be instructed to continue to apply pressure to the wound until bleeding has stopped.

Bleeding that persists after the initial phase of clot formation should be treated first with local measures, starting with direct pressure to the surgical site. Careful examination of the operative site with illumination and magnification and good suction can be invaluable to identify the source of bleeding. It is not uncommon to identify an incompletely formed clot, a "liver clot", that is mobile and continues to aggravate the site. Careful removal of the clot is critical to control the bleeding successfully. Use of local vasoconstricting agents, such as local anesthetics with a vasoconstrictor such as epinephrine, appropriate once the source of bleeding has been identified. If the vasoconstrictor is applied to the area prior to identification of the bleeding vessel, identification will be complicated. The wound may need to be repacked with a local hemostatic agent and sutured. Arterial bleeds that cannot be controlled with local measures should be treated with ligation or electrocautery. If bleeding persists, embolization, proximal vessel ligation, or other endovascular procedures may be required.^{3,4}

Pain

Etiology and prevalence

As with bleeding, postoperative pain is a side-effect of operative intervention. Pain associated with routine dentoalveolar procedures usually begins with the resolution of local anesthesia (6–12 hours) and typically peaks between 24 and 48 hours postoperatively.

Risk factors and prevention

Prevention of pain via intraoperative measures and adequate postoperative pain control measures is essential. Intraoperatively, minimizing tissue trauma and careful tissue manipulation will decrease inflammation and thus decrease pain. There is evidence that the administration of preoperative non-steroidal anti-inflammatory medications (salicylates, cyclooxygenase (COX)-2 inhibitors) can reduce the severity of postoperative pain.^{5–7} Postoperatively, the use of non-steroidal medications, as well as narcotic preparations with acetaminophen (APAP) (hydrocodone, oxycodone, tramadol) have been shown to be useful for treatment of moderate to severe postoperative pain.^{8–10} In addition, the use of long-acting anesthetics, e.g. 0.5% bupivacaine with 1:200 000 epinephrine, can be beneficial in delaying the onset of pain, which may allow the patient to start postoperative analgesics prior to the onset of pain. Some standard preparations for management of postoperative pain are listed in Table 10.1.¹¹

Swelling

Etiology and prevalence

Edema following the surgical removal of teeth and other routine dentoalveolar procedures is an expected

Table 10.1 Common medications used for postoperative pain control.¹²

Medication	Mode of action	Indication	Adult dose	Pediatric dose	Common side-effects
Acetaminophen (APAP)	Central prostaglandin synthesis inhibition	Mild to moderate pain	325–650 mg q4–6h not to exceed 4 g daily, 2 g daily in liver-compromised patients	<12 years of age, 10–15 mg/kg q4–6h, not to exceed 2500 mg daily	Hepatotoxic in high doses or when given in presence of ethanol
Ibuprofen/aspirin	Peripheral prostaglandin synthesis inhibition	Mild to moderate pain	Aspirin: 325–650 mg q4–6h not to exceed 3500 mg daily Ibuprofen: 200, 400, 600 q4–6h or 800 mg q8h not to exceed 3200 mg daily	Ibuprofen: >6 months of age 5–10 mg/kg PO q6–8h (suspension 50 mg/1.25 ml, 100 mg/5 ml)	GI upset, platelet suppression, renal hypoperfusion Consider coadministration of antacid or proton pump inhibitor
Opioids: Codeine Hydrocodone Oxycodone	Opioid receptor antagonist	Moderate to severe pain	In combination with APAP: 30 mg codeine, 300 mg APAP 5 mg hydrocodone, 500 mg APAP (Vicodin) 5 mg oxycodone 325 mg APAP (Percocet)	Codeine, 0.5–1 mg/kg, combine with APAP (see above dosing) q4–6h	Additive Constipation – consider coadministration of stool softener or laxative May cause drowsiness or sedation

Table 10.2 Common steroid preparations.^{11,15}

Medication	Preoperative evening	Day of surgery	Postoperative day 1	Postoperative day 2
Methylprednisolone sodium succinate (Solu-Medrol)	16 mg PO at bedtime for a morning case - Nothing for an afternoon case	- Morning case: 125 mg IV at start of case - Afternoon case: give 16 mg PO 4 hours prior to start of case; 125 mg IV at start of case - Night of surgery: 16 mg PO at bedtime	8 mg PO q6h	8 mg PO q6h
Methylprednisolone acetate (Depo-Medrol) long-acting	16 mg PO at bedtime for a morning case - Nothing for an afternoon case	- Morning case: 40 mg IM after local anesthesia administration - Afternoon case: 16 mg PO 4 hours prior to start of case; 40 mg IM after local anesthesia administration	Nothing	Nothing
Dexamethasone (Decadron)	8 mg PO at bedtime for a morning case - Nothing for an afternoon case	- Morning case: 16 mg PO 4 hours prior to start of case or 8–12 mg IV at start of case - Afternoon case: give 16 mg PO 4 hours prior to start of case; 16 mg PO 4 hours prior or 8–12 mg IV at start of case 8 mg PO night of surgery	16 mg PO in the morning	Nothing

finding during the postoperative course. The onset of swelling is typically between 12 and 24 hours following the procedure, with a peak swelling noted 48–72 hours postoperatively. Swelling typically begins to subside at 4 days postoperatively, with most patients experiencing resolution of surgical edema within 1 week postoperatively.^{3,13}

Prevention and treatment

It is important to inform patients of this time course and that swelling is an anticipated postoperative

finding. In the early postoperative period, the use of ice may help with management of swelling. In addition, patients should be told to sleep with the head of their bed elevated and not to sleep on their side, so as to avoid dependent swelling. Finally, perioperative steroids may be used to prevent swelling in patients undergoing significantly invasive procedures (e.g. third molar extraction). While the use of perioperative steroids may produce moderate decreases in swelling, these medications are typically short in action. Standard preparations for use are listed in Table 10.2.¹⁴

Postoperative complications

Surgical site infection

Etiology and prevalence

Because the oral cavity is home to a wide variety of bacterial flora, any intraoral wound will be exposed to a broad spectrum of aerobic, anaerobic, and facultative organisms with pathogenic potential. As such, postoperative infections should be primary among concerns for the practitioner when performing oral surgical procedures. Though the routine use of antibiotics for prevention of postoperative infections is still debated,¹⁶ there are several measures that can be implemented to reduce the likelihood of postoperative wound infection. A recent large-scale prospective study suggested that the infection rate following third molar removal was approximately 1%.¹⁴ For other, less invasive dentoalveolar procedures, the infection rate is typically lower.

Prevention

Prevention of postoperative infection begins with identification of the patient at risk. A number of studies have demonstrated that the incidence of postoperative inflammatory complications increases with age, smoking, pre-existing infection/pathology in the surgical area, oral contraceptive use, and lack of surgical experience. When dealing with impacted teeth, mandibular third molars have been shown to have a higher rate of postoperative infections than maxillary teeth.

As with other common complications, careful tissue management, debridement/curettage of necrotic/infected tissue, and thorough irrigation of the wound site will help to reduce the bacterial inocula within the wound site and reduce the possibility of infection.

Treatment

Patients presenting with infections will typically complain of persistent pain and swelling that is not improving with time, a foul taste, drainage from the wound, and limitation of jaw motion (trismus). Fever is variable and depends on the magnitude of the infection. Early recognition of an infectious process, typically a cellulitis, requires prompt treatment with an empiric course of antibiotics with broad-spectrum coverage for Gram-positive and anaerobic organisms (Table 10.3). If the symptoms have persisted for more than 48–72 hours after the procedure, an abscess may have formed, in which case incision and drainage of the abscess may be indicated, with collection of exudate for culture and sensitivity testing to guide antibiotic therapy (Fig. 10.1). Prompt recognition and treatment are necessary to prevent the spread of infection into the submandibular, sublingual, submental, retropharyngeal spaces and spaces of the deep neck, which can result in airway compromise and the necessity for emergency airway management.

Alveolar osteitis

Prevalence and etiology

Among the most common complications associated with oral surgical procedures, specifically the removal of impacted teeth, is alveolar osteitis (AO), or “dry socket”. The reported incidence is as high as 30% in some studies, though there exists a wide variation in reported incidence due to inconsistent diagnostic criteria.^{3,18} This condition, which was classically thought to be infectious in nature, is now understood to be associated with malformation, disruption, or other loss of a newly formed blood clot from an extraction socket. Patients presenting with AO will usually complain of a severe throbbing, radiating pain, often

Table 10.3 Common antibiotic formulations for treatment of surgical site infections.^{12,17}

Medication	Indication	Coverage	Adult dose/route of administration	Pediatric dose/route of administration
Penicillin VK	First line for odontogenic infections	Streptococci, oral anaerobes	250–500 mg PO q6h for 7 days	25–50 mg/kg/day q6–12h for 7 days (suspension 125, 250 mg/5 ml)
Cephalexin, Cephadroxil	Need for bacteriocidal broader coverage	Gram-positive cocci, some Gram-negative rods, oral anaerobes	250–500 mg PO q6h for 7 days	25–50 mg/kg/day divided q12h for 7 days, severe infections 100 mg/kg/day (suspension 100, 125, 250 mg/5 ml)
Amoxicillin	Need for broad spectrum, infections >3 days	Gram-positive cocci, <i>Escherichia coli</i> , <i>Haemophilus influenzae</i> , oral anaerobes	250–500 mg PO q8h or 500–875 mg PO q12h for 7 days	40 mg/kg/day PO divided q8h or 45 mg/kg/day q12h for 7 days (suspension 125, 250 mg/5 ml)
Clindamycin	Need for broad spectrum, oral anaerobes, penicillin-allergic patient	Gram-positive cocci, anaerobes	150–450 mg PO q6h for 7 days	8–25 mg/kg/day suspension PO divided q8h or q6h for 7 days (suspension 75 mg/5 ml)

Fig. 10.1 Postoperative surgical site infection. Purulent exudate can be seen emanating from the surgical site following extraction of tooth 32.

associated with a malodor from the surgical site. Trismus is an associated sign, related more to pain than swelling. Recognition of AO is based on the presence of new-onset severe pain, typically 3–5 days postoperatively, at which point pain and swelling associated with the operation should be beginning to subside. The lack of constitutional symptoms (fever), significant swelling, or intraoral discharge may help to distinguish AO from a surgical site infection. This distinction is important, since antibiotic treatment will not resolve AO. Physical exam findings may include a crypt-like socket with exposed bone and erythematous soft-tissue margins, food debris, or other detritus in the socket and extreme tenderness to palpation (Fig. 10.2). Radiographic examination should also be obtained to rule out the presence of a retained tooth structure or other surgical site complication, such as alveolar fracture.

Prevention

Preoperatively, there are a number of risk factors that have been identified that should alert the vigilant practitioner of the patient at risk. As with postoperative infections, age, oral contraceptive use, surgical experience, smoking, and mandibular surgery have been associated with AO.¹⁸ In addition, poor oral hygiene and pre-existing infections have been shown to increase the risk for AO.

Intraoperatively, thorough lavage of the surgical site has been shown to be associated with a decreased

Fig. 10.2 Alveolar osteitis. This patient, a 30-year-old smoker, who was also on oral contraceptives, presented with severe pain of sudden onset 4 days after extraction of tooth 20. The clot is absent and exposed bone can be seen (arrow).

incidence of AO.¹⁹ The use of topical medicaments and antibiotics, clot stabilizers (Gelfoam), platelet-rich plasma, and medicated mouthrinses have also been suggested for prevention of AO, with varying results.^{20–23}

Treatment

Once a diagnosis of AO has been made, treatment should be instituted immediately. As the condition is self-limiting, the treatment is supportive, with pain control being the primary goal. Treatment typically consists of gentle irrigation of the wound area with warm saline and application of medicated packing to the area, e.g. eugenol dressings, and aggressive use of oral analgesics. The packing should be changed every 24 hours until symptoms subside.

Fractures

Prevalence and etiology

While rare, fractures of the dentoalveolar process or mandible should be considered in the differential diagnosis of persistent pain or swelling after dentoalveolar procedures. Fractures are the result of using excessive force during tooth extraction (Fig. 10.3). If unrecognized and untreated, such fractures can lead to malocclusion, malunion, infection, and paresthesia.

Prevention

Preoperatively, there are few risk factors for fracture that have been identified. There is some evidence to suggest that age is a risk factor for fractures, presumably because of the loss of bone density, elasticity, and strength which are common findings in elderly patients. Atrophic mandibles or mandibles with large intrabony lesions are at risk for fracture.

Fig. 10.3 Mandibular angle fracture upon attempted extraction of mandibular third molar. (a) Preoperative radiograph showing vertically impacted tooth 32. (b) The tooth has been partially extracted, with the roots remaining; there is a fracture of the mandibular angle. (c) After reduction of right mandibular angle fracture. (Photos provided courtesy of Leonard B. Kaban, DMD, MD.)

Treatment

Recognition of the fracture is the most important management. Intraoperatively, recognition of an alveolar process or mandibular fracture can result from observing a mobile alveolar or mandibular segment or malocclusion. Postoperatively, any patient complaining of malocclusion, pain and swelling disproportionate to the procedure, tooth displacement or mobility, or persistent numbness should be evaluated for a possible fracture.

Once a fracture is identified, typically with the aid of imaging studies, e.g. periapical or panoramic radiographs or computed tomography (CT), treatment is guided by the nature of the fracture and functional limitation. Treatment ranges from dietary modifications (blenderized diet) and early immobilization to reduction and fixation of the fracture.

Root fracture

Prevalence and etiology

Root tip fractures are common after tooth extraction, especially in posterior, multirooted teeth. Fracture of the roots, or root tips, is typically due to excessive forces applied during extraction with inadequate separation of the roots from the extraction socket and is commonly unavoidable due to the root anatomy and bone quality. When such forces are applied, the torque generated will typically cause a fracture at the junction between that portion of the root still attached to the socket and that portion already freed from the alveolar wall.

Prevention

The prevention of root fractures is primarily based on use of proper surgical technique, minimizing excessive forces, and carefully ensuring that teeth are adequately elevated and mobilized prior to luxation. Recognition of teeth at risk for root fracture is also an important preventative measure. Multirooted posterior teeth, roots that are curved, canines or other anterior teeth that have root dilacerations, or teeth with widely spaced, thin roots all have an increased risk for fracture. Inadvertent root fractures can be avoided by operative planning and prudent sectioning of a tooth prior to elevation and removal.

Treatment

The most important step in treating a fractured root or retained root tip is recognition that such an incident has occurred. Once the tooth has been removed, it should be carefully inspected to confirm that the roots were removed completely. Reconstitute the fragments of a sectioned tooth to confirm complete removal.

If a root fracture is noted, the socket should be irrigated thoroughly and an attempt should be made to directly visualize the retained root/ root tip. For teeth without preoperative evidence of periapical pathology or infection, small root tips (<3mm) can be left in place without adverse effects. In fact, for posterior teeth, the risk of causing damage to the maxillary sinus or inferior alveolar nerve may often outweigh the risk of leaving the fragment in place.

If there is associated pathology with the tooth preoperatively, the root fragment should be removed. Once the fragment is directly visualized, root tip

picks/elevators should be used to carefully separate the fragment from the alveolar socket, with special care taken not to apply apical pressure to the fragment. This gentle manipulation should be done until the root is mobilized, at which point it can be removed.

Root or tooth displacement

Prevalence and etiology

Displacement of root tips or tooth fragments is an uncommon but distressing complication nonetheless. Given the proximity of various fascial spaces to maxillary and mandibular third molars, displacement of tooth fragments can occur into the infratemporal fossa and maxillary sinus or submandibular space and inferior alveolar canal, respectively.

Prevention

Displacement of tooth fragments into these fascial spaces can often be prevented by using careful surgical technique. For example, when elevating an impacted maxillary third molar, the use of a periosteal elevator posterior to the distal aspect of the crown can serve as a barrier to displacement into the infratemporal fossa. In the event of displacement into the infratemporal fossa, a minimal attempt should be made to visualize the fragment and remove it. If this attempt is unsuccessful, the wound should be closed and the patient should be given a course of antibiotics. Future exploration of the region should be anticipated and CT, plain film imaging or both should be obtained to aid in localization and surgical treatment planning.

Careful examination of preoperative radiographs can be useful in evaluating the association between the roots of impacted maxillary third molars and the maxillary sinus. In older patients, or those with significant periodontal disease, pneumatization of the

maxillary alveolus can increase the likelihood of an association between the roots of the teeth and the maxillary sinus. In these cases, careful attention must be directed to avoiding excessive apical pressure to the teeth during the process of extracting teeth.

Treatment

In the event that a root fragment or tooth is displaced into the maxillary sinus (Fig. 10.4), the first step in treatment is localization of the fragment and prevention of further displacement. Typically this can be achieved by seating the patient in the upright position and obtaining periapical radiographs of the region of interest. In the event that a root or fragment is visualized, various methods can be used for retrieval. The simplest method is forcing positive pressure through the sinus to displace the root – this can be accomplished by closing the nostrils and having the patient attempt to exhale through the nose. Alternative methods include attempting to remove the fragment using a thin suction tip or packing the socket with iodoform gauze and removing the gauze in a smooth stroke, hoping that the fragment will be caught in the gauze. In the event that such measures prove unsuccessful, the maxillary sinus can be explored to directly visualize and remove the fragment. This can be done as a simultaneous procedure or at a future visit. If done at a future visit, the patient should be placed on sinus precautions (Table 10.4), antibiotics and nasal decongestants.

Table 10.4 Sinus precautions.

Sinus precautions	Ancillary medications
No nose blowing	Pseudoephedrine (30 mg, PO, q4h prn congestion for 7 days)
Open-mouthed sneezes	Amoxicillin 875 mg + clavulanic acid 125 mg PO, q12h for 14 days or similar coverage
No smoking	Saline nasal spray (two puffs, each nostril, q4h for 7 days)
No straws	

Fig. 10.4 Tooth displaced into maxillary sinus.

Displacement of mandibular teeth into either the submandibular space or inferior alveolar canal is a rare occurrence. However, given the vital structures in these regions, any suspicion of displacement must be evaluated fully. Visualizing any fragments is best accomplished using periapical films, with occlusal films in addition for submandibular space invasions. Once the fragment is identified, a gentle attempt should be made to remove the fragment from the inferior alveolar nerve (IAN) canal or the submandibular space, but care should be taken not to compromise the spaces and further displace the tooth. In the event that the fragment cannot be easily removed, delayed removal may be indicated and the patient should be placed on antibiotics. For fragments in the IAN canal, if the patient does not demonstrate any signs of infection or paresthesia in the postoperative course, the fragment may be left without concern. For fragments in the submandibular space, exploration of the region with lingual dissection and separation of the mylohyoid muscle from the mandible is indicated approximately 6 weeks after the initial operation. This delay allows for tissue fibrosis to occur around the displaced fragment, thereby stabilizing its position.

Oroantral communication

Prevalence and etiology

Following extraction of maxillary posterior teeth, oroantral (sinus) communications are common, commonly unrecognized, and do not need treatment. Persistent, symptomatic oroantral communications

are uncommon with a frequency of $<1\%$.³ Oroantral communications may result from excessive manipulation of the operative site or poor technique. It should be readily acknowledged that communications typically result from intimate anatomic associations between the roots of the teeth and the floor of the maxillary sinus and may be unavoidable (Fig. 10.5).

Prevention

As with displacement of teeth into the maxillary sinus, prevention of oroantral communications starts with identification of the patient at risk. Evaluation of preoperative radiographs for any evidence of encroachment of the roots upon the floor of the sinus should alert the surgeon to the likelihood of this complication. Upon removal of the tooth, the socket should be curetted gently, or not at all. If the tooth is not removed completely, judicious exploration should be undertaken, so as not to: (1) displace the remnant into the sinus; or (2) perforate the sinus floor while attempting to remove the fragment. A self-limiting oroantral communication may be an unavoidable side-effect of tooth removal due to the anatomic relationship between the roots and the sinus. Informing the patient of a high likelihood of an oroantral communication prior to tooth removal is preferable to explaining it after tooth removal.

Treatment

Diagnosis of a sinus communication is often made by having the patient force air through the nasal cavity while the nares are closed. If a large communication

Fig. 10.5 Persistent oroantral communication following extraction of multiple periodontally involved teeth. The sinus on the right side is partially obliterated with inflammatory tissue (arrow a) and the bony defect can be readily visualized (arrow b) and is much larger than the apparent size of the lesion based on clinical examination (arrow in clinical photograph). Preoperative panoramic radiograph demonstrates close proximity of the roots to the maxillary sinus and a poorly defined margin of sinus floor around the apices of the dental roots.

exists, air bubbles should be visible within the socket. This method may prove ineffective for small communications.

In the event that a communication is discovered, either by tactile sensation or forced air maneuver, the size of the defect and patient complaint guide treatment.²⁴ As a general principle, any patient with a communication should be placed on sinus precautions, antibiotics, and nasal decongestants (Table 10.4).

Most oroantral communications heal spontaneously with little intervention. At the time of the procedure, primary closure of the extraction socket is not indicated. The patient should be placed on broad-spectrum antibiotics, e.g. penicillin or clindamycin, and sinus precautions. Monitor the patient closely over the postoperative period to confirm closure of the oroantral communication. If an oroantral fistula develops, standard procedures to produce a layered closure of the wound and management of the sinus are indicated. Clinicians should remember that the size of the visible fistula is much smaller than the actual bony defect (Fig. 10.5).

Chapter 11a

Normal Wound Healing

Anh Le and Vivek Shetty

This chapter covers the description of the inflammatory phase, proliferation phase, and maturation and remodeling phase of normal wound healing. Specialized healing, to include skin and oral mucosal healing, bone and extraction socket healing, and implant site healing, are also discussed. The use of adjuvants to wound healing, including growth factors and hyperbaric oxygen, is covered, as are skin substitutes.

severe tissue loss, or poor apposition of the wound margins, the healing process is prolonged with excess granulation and connective tissue formation, and is described as healing by *second intention*. Occasionally, the surgeon may attempt healing by *third intention* to address the challenges posed by infected or contaminated traumatic wounds with severe tissue loss. Here, the surgical repair is staged by allowing the wound to granulate initially and heal by second intention, followed subsequently by delayed primary closure.

Fig. 11a.1 illustrates the normal biology of healing, which consists of several distinct but overlapping phases including the inflammatory, proliferative, and remodeling phases.¹ Although rates and patterns of healing depend on a host of local, systemic, and surgical factors, the phases of oral mucosal healing closely approximate dermal healing. In general, wounds in the oral cavity appear to heal faster than dermal wounds. Oral wounds, despite being exposed to a bacteria-laden, moist, and seemingly hostile environment, heal perfectly well and re-epithelialize rapidly, with minimal or no scar formation.

Physiology

Any traumatic insult that creates a wound also initiates a complex cascade of closely synchronized cellular and molecular events that drive the process of tissue restitution. Normal healing is a primal life-preserving property that protects the integrity of the organism as a whole by repairing the damaged tissue architecture. Although normal healing may slightly differ from tissue to tissue, the components of the wound healing process are quite similar throughout the body. From a surgical viewpoint, the nature of the healing process is dictated by several factors, including the anatomical site injured, the type of tissue involved, the timing of the repair, and how well the wound margins are approximated. Early primary closure with adequate apposition of the wound margins usually results in healing by *first intention* wherein the wound heals uneventfully with minimal scar formation. In the presence of wound infection,

Inflammatory phase

Following injury the wounded site attempts to regain its normal physiologic state (homeostasis). Blood coagulation and platelet aggregation generate a fibrin clot within the vessel lumen and provide a provisional matrix for cell migration. Pro-coagulant factors, including fibrinogen, fibronectin and thrombospondin, are released by the injured cells and initiate the coagulation cascade. Concomitantly, the injured tissue and platelets begin to release several wound healing modulators including platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), and transforming growth factor β (TGF- β). The local cytokines and chemo-attractants recruit inflammatory cells which begin to remove damaged tissues and bacteria from the injured area. Clinical signs include localized edema, pain, redness, and increased warmth at the wound site. Neutrophils are the predominant inflammatory cells during the initial

Fig. 11a.1 The three overlapping phases of wound healing.

2–3 days following injury, but are rapidly outnumbered by macrophages derived from mobilized monocytes (Fig. 11a.2a).

Proliferation phase

The proliferation phase is a period of intense replication of cells and is characterized by the migration and proliferation of fibroblasts and smooth muscle cells into the wound milieu. Fibroblasts are the major cells responsible for the production of collagen and proteoglycans. They interact with the surrounding matrix via receptors known as integrins that regulate the level of collagen gene expression and collagenase induction. Collagen restores strength and integrity to the reparative tissue, whereas proteoglycans function as moisture storage. Concurrent with these events is the process of neovascularization, whereby new blood vessels are formed and lymphatics are recanalized in the healing tissues. This essential process re-establishes transport of the nutrients and oxygen to the local injured site. In a synergistic way, the new capillaries supply nourishment to the developing collagen, while the collagen fibers structurally support the new capillary beds. Epithelial cells originating from hair follicles, sebaceous glands, and margins of the wound edges proliferate and resurface the wound above the basement membrane. In contrast to skin, the process of re-epithelialization progresses more rapidly in the oral mucosal wound. The oral epithelial cells migrate directly on to the moist, exposed surface of the fibrin

clot instead of under the dry exudate (scab) of a dermal wound.² The rapid re-epithelialization protects the wound from further insults from the oral environment, including food debris, foreign particles and microorganisms (Fig. 11a.2b).

Maturation/remodeling phase

The remodeling phase is the final stage of tissue repair and is distinguished by a continual turnover of collagen molecules, as precursor collagen is broken down and new collagen synthesized. The tensile strength of the wound is gradually restored as the collagen fibers are realigned and increasingly cross-linked to each other. The maximal tensile strength of a healed wound is reached in 6–12 months post injury but never reaches the strength of unwounded tissue. Eventually, active collagen synthesis achieves equilibrium with collagenolysis. The homeostasis can be impacted by disruptive processes such as poor oxygen perfusion,³ lack of nutrients, and wound infection, which favor collagen breakdown and wound dehiscence.

Specialized healing

Skin and oral mucosa (including grafts)

Healing of both oral mucosal and dermal wounds proceeds through the same stages – hemostasis,

Fig. 11a.2 (a) Initiation of wound healing. Tissue injury precipitates blood clotting, platelet aggregation, and migration of leukocytes, including neutrophils and macrophages, to the site of injury. Initially, the blood clot is composed of fibrin and fibronectin, serving as a scaffold for cell migration and aggregated platelets, which release growth factors into the surrounding tissue. By day 3, the clot has contracted and accumulated numerous neutrophils, which phagocytose and kill microorganisms, and macrophages, which produce and secrete growth factors into the wound environment. Activated fibroblasts and endothelial cells in the periwound stroma begin to express integrins and secrete growth factors. (b) Repair of acute wound. Under normal physiologic conditions the wound continues to heal with an ingrowth of granulation tissue composed of fibroblasts, macrophages, and establishment of neovasculature. Marginal epidermis migrates over the newly forming tissue. Proteases restricted to the leading edge of migrating tissue cells facilitate their invasion of the clot and ingrowth into the wound. Many growth factors released by platelets and secreted by macrophages during the initial phase of healing stimulate tissue cells as they move into the wound. (Reprinted with permission from Clark R. *et al.*, *J Invest Dermatol.* 2007 May; 127(5): 1018–29. Copyright © 2007 Macmillan Publishers Ltd.)

inflammation, proliferation, and remodeling of the extracellular matrix. Differences between the two tissues relate mostly to the immediate environment (moist, saliva-bathed oral wounds versus the dry, air-exposed dermal wounds), the rapidity of the re-epithelialization, and the lack of scar formation. Oral mucosal wounds heal by first or second intention. Healing by first intention occurs with the apposition of the incised wound margins without exposure to the oral environment and minimal loss of tissue.

Partial-thickness wounds

Partial-thickness wounds, generated by abrasions or by graft harvesting, usually heal by epithelialization from wound margins and from remnant epidermal appendages, such as hair follicles and ducts in the wound bed. Following hemostasis, the partial-thickness wound forms a scab in skin or a fibrinous pseudomembrane in oral mucosa. Topical dressings in the form of fibrin matrix or synthetic materials to

keep the wounds moist can help re-epithelialization and decrease wound sensitivity. Gauze dressings impregnated with various antibacterial substances and occlusive plastic films are often used for this purpose. Systemic antibiotics do not work well for this, and should be used only if there is cellulitis in the surrounding tissues.⁴

Full-thickness wounds

Full-thickness injuries imply a complete loss of the epithelium and its appendages. Full-thickness wounds can be generated by tumor resection, trauma, burns, infection, radiation, or vascular compromise. Left alone, these injuries will heal gradually by granulation and epithelialization. However, infection may intervene before the protective epithelium is completely restored. If the wound bed is relatively septic and well vascularized, a full- or partial-thickness skin graft can be placed to enhance healing. An alternative is the use of a vascular flap to cover the soft tissue defect.

Bone/extraction wounds

Healing of an extraction socket is a specialized example of healing by second intention.⁵ Immediately after the removal of the tooth, the clot is formed in the alveolar socket within the first 24–48 hours, followed by engorgement and dilation of blood vessels, leukocytic migration, and formation of a fibrin layer. In the first week, the fibrin clot reorganizes into a temporary scaffold for cell migration and angiogenesis. Epithelium at the wound periphery grows over the surface of the organizing clot. Osteoclasts accumulate along the alveolar bone crest setting the stage for active crestal resorption. In the second week, the clot continues to get organized through fibroplasia and neoangiogenesis. Trabeculae of osteoid slowly extend into the clot from the alveolus and osteoclastic resorption of the cortical margin of the alveolar socket is more distinct. By the third week, the extraction socket is filled with granulation tissue and early woven bone islands form around the periphery of the wound. The surface of the wound is completely re-epithelialized with minimal or no scar formation. Active bone remodeling by deposition and resorption continues for several more weeks. Radiographic evidence of bone formation does not become apparent until 6–8 weeks following tooth extraction. As bone remodeling proceeds, the extraction site becomes less distinct and is inconspicuous after 6–8 months.

Occasionally the blood clot fails to form or may disintegrate causing a localized alveolar osteitis. In such instances, healing is delayed considerably and the socket fills gradually. Because of the absence of a healthy granulation tissue matrix, the apposition of regenerated bone to remaining alveolar bone takes place at a much slower rate. Compared to a normal socket, the infected socket remains open or partially

covered with hyperplastic epithelium for an extended period.

Implant healing

Wound healing around dental implants involves two processes, the healing of bone at the implant interface and the healing of soft tissue to the implant. Bone healing at the implant interface varies depending on the bone density at the implant site. Cortical bone requires a longer healing time than trabecular bone. At the implant surface, glycosaminoglycans secreted by osteocytes were initially deposited to coat the oxide layer, followed by a layer of osteoid or woven bone synthesized by osteoblasts. The greater the implant surface, the better the implant osseointegration. Thus, longer or wider-diameter implants will have more surface area available for osseointegration. The initial deposition of bone must occur before epithelium migration over fibrous connective tissue. The use of woven membranes to prevent fibroblast migration and soft tissue in-growth was initially proposed to selectively aid bone formation. Conditions that contribute to no movement during healing are the primary factor for a direct bone-to-implant interface. Other factors associated with implant failure include diabetes mellitus, head and neck radiation, and smoking.⁶ Once the bone-to-implant interface is established, the interface approaches the properties of the strongest load-bearing lamellar bone.

Wound healing adjuncts

An increased understanding of the wound healing processes has generated a heightened interest in manipulating the wound microenvironment to facilitate healing. The traditional passive ways of treating wounds are rapidly giving way to approaches that actively modulate the environment of the wound to accelerate the healing process. These approaches include treatments that selectively jump-start the wound into the healing cascade, stimulate cell recruitment and proliferation, increase oxygenation and perfusion of the local tissues, or mechanically protect the wound from further insults.

Growth factors

Various topical exogenous recombinant growth factors have been investigated as agents to accelerate the wound healing process. These include platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), epidermal growth factor (EGF), transforming growth factor (TGF), basic fibroblast growth factor (bFGF), tumor necrosis factor (TNF), and interleukin (IL). However, the potential of these extrinsic agents has not yet been realized clinically and may relate to figuring out which growth factors to put into the wound – and when and at what

dose. To date, only a single recombinant growth factor – recombinant human platelet-derived growth factor-BB form (PDGF-BB: Becaplermin, Ortho-McNeil Pharmaceutical, Raritan, NJ) – has been approved by the US Food and Drug Administration for the treatment of cutaneous ulcers, specifically diabetic foot, ankle, or leg ulcer. Results from several controlled clinical trials show that PDGF-BB topical gel was effective in healing lower extremity diabetic ulcers and significantly decreased their healing time when compared to the placebo group.^{7,8}

More recently, recombinant human keratinocyte growth factor 2 (KGF-2: Repifermin, Human Genome Sciences, Inc., Rockville, MD) has been shown to accelerate wound healing in experimental animal models. It enhances both the formation of granulation tissue in both young and old rabbits and wound closure of the human meshed skin graft explanted on athymic nude rats.^{9,10} The safety assessment of the drug showed that KGF-2 was well tolerated in humans with no differences in adverse events.¹¹

Hyperbaric oxygen therapy

Hyperbaric oxygen therapy (HBOT) is occasionally used in wound healing to raise tissue oxygen tension to a level that facilitates healing.¹² In HBOT, 100% oxygen is delivered to the patient at pressures between 1.5 and 2.4 atmospheres. This stimulates the growth of fibroblasts and endothelial cells, increases the killing ability of leukocytes and is lethal for anaerobic bacteria. Multiple studies of HBOT in the treatment of human diabetic patients suggest that HBOT can be an effective adjunct in the management of diabetic wounds.¹³ Animal studies suggest that HBOT could be beneficial in the treatment of osteomyelitis and soft tissue infection.^{14,15} Adverse effects of HBOT are barotrauma of the ear, seizure and pulmonary oxygen toxicity.

Skin substitutes

Immediate wound coverage is critical for the acceleration of wound healing. When the surface area is large, wounds can be covered by synthetic and natural dressings. The human skin substitutes available are grouped into three major types and serve as excellent alternatives to autografts.^{16,17} The first type consists of grafts of cultured epidermal cells with no dermal components (Epicel, Genzyme Tissue Repair Corp., Cambridge, MA). The second type has only dermal components (Alloderm, Life Cell Corp., Woodlands, TX; Dermagraft, Advanced Tissue Sciences Inc., La Jolla, CA). The third type consists of a bilayer of both dermal and epidermal elements (Apligraf, Organogenesis Inc., Canton, MA; Integra, Johnson & Johnson Medical, Integra Life Sciences Corp.,

Plainsboro, NJ). The chief effect of most skin substitutes is to promote wound healing by stimulating the recipient host to produce a variety of wound healing cytokines. The use of cultured skin to cover wounds is particularly attractive inasmuch as the living cells already know how to produce growth factors at the right time and in the right amounts.

Chapter 11b

Compromised Wound Healing

Gösta Granström

In this chapter, the definitions of compromised wounds are described, as are possible background factors for a wound to be non-healing. Known factors at the tissue, cellular, and subcellular levels that inhibit healing are discussed. An evidence-based approach to handling of compromised wounds is given. Specific compromised wounds such as those appearing in irradiated tissues are presented, with special reference to osteoradionecrosis. The chapter also discusses other factors that can predispose to a compromised wound, including old age, osteoporosis, and diabetes mellitus. Finally, bisphosphonate-induced osteonecrosis is presented.

Introduction

It is of the utmost importance for the oral and maxillofacial surgeon to realize that the patient, in whom surgery is to be performed, might have compromised tissues. The most common of these is the irradiated patient. A standard surgical procedure in such a patient could be associated with complications, and

result in a non-healing wound, tissue breakdown, bone sequestra, fistulas, and continuous draining. If, on the other hand, the surgeon is aware of the possible risks, precautions might be taken to prevent these problems ahead of surgery.

Compromised wounds

If wound healing fails to follow a normal sequence of events, then healing may be defined as compromised. A common feature of compromised wounds is that they appear arrested at a stage of inflammation. Continuous inflammation and the presence of bacteria may result in the generation of exudates containing disordered cytokine / growth factor network, high levels of proteolytic enzymes that destroy tissue proteins, growth factors, and extracellular matrix.^{1,2} Cells from the wound margin proliferate, but fail to migrate over the wound bed to re-epithelialize the wound because the extracellular matrix degrades and the wound remains open.

Microbiology of compromised wounds

Detailed microbiological investigations have shown that the wound bacteria are polymicrobial, involving both aerobic and anaerobic bacteria.³ Wound contamination occurs primarily from sources in close proximity to the wound site such as the surrounding skin, nares or mouth. In particular, the oral cavity is abundantly populated with a wide variety of microorganisms, where anaerobic bacteria predominate. In compromised wounds, the presence of devitalized tissue, hypoxia, and ischemia can stimulate microbial growth and hence the microbiology of these wounds is often complex. A diversity of both aerobic and anaerobic bacteria is common, and the prevalence of anaerobes has been observed particularly in infected compromised wounds.³ This may, in part, be attributed to the fact that many of the anaerobes commonly

found can possess a variety of virulence factors that impair the host response, especially different proteolytic enzymes. Interactions between aerobic and anaerobic bacteria are known to occur in compromised wounds, causing an increase in overall pathogenic effect.⁴ Aerobic bacteria can induce hypoxia by consuming local oxygen, thus favoring anaerobes. Compromised wounds are often densely populated with Gram-negative bacteria, and endotoxin content in the wound can be high.³

Another important factor in the compromised wound is the blood supply. Blood supports the wound with oxygen, nutrients, and inflammatory cells, all of which are necessary for healing. Oxygen is critical to wound healing, stimulating collagen production and migration of epithelial cells. Oxygen can further inhibit bacterial growth (anaerobes), and stimulate the number and migratory activity of polymorphonuclear cells (PMNs).⁴ Low local tissue oxygen (pO_2) is known to reduce the bacterial inhibitory capacity of PMNs. This has been reported at pO_2 below 30 mmHg^{5,6} and similar or lower values have been recorded in compromised wounds.⁷ In well perfused tissue with pO_2 above 40 mmHg, the probability of wound healing is higher.⁴ At suboptimal tissue pO_2 , the accumulation of hypoxic or anoxic tissue provides an ideal growth environment for a wide variety of microorganisms. Oxygen is thus critical to many processes that can influence the probability of healing in a compromised wound.

Proteolytic enzymes

The marginal cells of the wound are able to secrete different proteolytic enzymes. In the normal healing wound this activity is controlled. Proteases are required to destroy necrotic tissue and extracellular matrix to allow migration of cells and capillaries over the wound. Further, extracellular matrix is remodeled so that it achieves maximum strength. However, in compromised wounds there can be a lack of inhibitory factors to regulate protease activity. There can also be an overproduction of proteases. This loss of control of proteolytic enzyme activity has great potential for disruption of the healing process.⁸

Growth factors and extracellular matrix

The increase in protease activity in compromised wounds can result in degradation of different growth factors needed for regulation of the healing process.^{9,10} Extracellular matrix is primarily produced by fibroblasts. It determines the strength and elasticity by regulating collagen and elastin production. Fibronectin and laminin, also known as proteoglycans, are found in various combinations depending on wound age.⁸ While the mechanical properties of

the matrix are important for tissue function it is clear that it also acts as a reservoir for growth factors when required during healing.¹¹ Additionally matrix components such as vitronectin bind to surface cells and induce them to migrate over the wound surface as part of the re-epithelialization process.¹² Destruction of matrix by uncontrolled protease activity is believed to be an important factor preventing healing of compromised wounds.⁸

Treatment possibilities

In order to improve the possibility for healing of the compromised wound, it is necessary to improve the local environment so that it is unfavorable to microorganisms and favorable to the host repair mechanisms. Consequently, the removal of necrotic tissue, stimulation of endogenous antimicrobial and proteolytic activities, and the use of supplemental agents to address aspects of wound pathogenesis are necessary for the progression of wound healing.

Prevention of infections

Compared to compromised wounds, infection in postsurgical wounds is relatively predictable and can be significantly influenced by preoperative and intraoperative procedures. In situations where excessive bacterial contamination is expected, the probability of wound infection is greatly increased, and consequently prophylactic antibiotic therapy may be helpful.^{13,14}

Oxygen tension of tissues

Tissue oxygen tension is a key factor to prevent wound infection.⁵ A study to test different oxygen tension levels showed that the infection rate in patients receiving 80% inspired oxygen during and immediately after surgery was 54% less than in patients receiving 30% inspired oxygen (infection rates of 5.2% and 11.2% respectively).¹⁵ Hyperbaric oxygen therapy (HBOT), involving the intermittent inhalation of 100% oxygen at pressures greater than 100 kPa, has also been used as an adjunctive therapy in aggressive soft tissue infections and compromised wounds.¹⁶ Tissue oxygen levels of 400–500 mmHg achieved by HBOT facilitate the oxidative bacterial killing capacity of PMNs, directly inhibit growth of anaerobic bacteria, and promote collagen synthesis by fibroblasts.¹⁶ It has recently been shown that HBOT and basic fibroblast growth factor (bFGF) act synergistically, which may further promote healing in the compromised wound.¹⁷

Debridement (removal of necrotic tissue)

The presence of devitalized, necrotic tissue, and wound exudates causes compromised wounds.^{18,19}

Removal of such tissue is therefore important. Debridement can be achieved in several ways, and the choice of method is normally determined by the surgeon. With life-threatening medical conditions, such as necrotizing soft tissue infections and infected burn wounds, aggressive surgical debridement and intensive antibiotic therapy are essential to limit tissue loss and preserve life.^{20,21} Surgical removal of necrotic tissue, together with jaw reconstruction, is widely used in maxillofacial surgery for compromised wounds, especially of the lower jaw. This facilitates the restoration of the local blood supply, which is essential for healing. However, repeated surgical debridement of a non-healing wound can be traumatic to the patient and consequently slower and more passive topical therapies are often preferred for routine maintenance.

Another form of debridement that is occasionally used for removal of necrotic tissue and can be termed biosurgery, is maggot therapy. Maggots can lyse and ingest necrotic tissue and reduce bacterial growth. Secretions in the gut of the maggot are believed to have antimicrobial properties, with efficacy against *Staphylococcus aureus* and different streptococci.²²

Regulation of the amount of tissue exudate is also important for wound healing.¹⁸ Both the volume and composition of wound exudate can influence healing, and in compromised wounds, proteinase-rich exudates are likely to delay healing and cause damage to surrounding intact skin. Excess exudate is traditionally managed by a combination of absorbent dressings and topical antimicrobial agents. Vacuum therapy is sometimes used in infected and compromised wounds. This involves application of subatmospheric pressure (less than 100 kPa) to an enclosed wound environment. It has been reported to restore blood flow, remove excess exudate, reduce wound bacterial growth, reduce tissue edema, and improve granulation tissue formation.^{23,24}

Regulation of proteolytic activity

As discussed earlier, the presence of endogenous or exogenous proteinase activity can contribute to poor healing in compromised wounds. Consequently, therapeutic aims to regulate proteases, different enzyme inhibitors, and oxygen metabolites, as well as strategies to affect bacterial proteinase activity have been developed.²⁵ In the future, strategies will probably focus on good wound care practices involving compression therapy to reduce chronic inflammation, and advanced dressings that can facilitate regulation of proteinase activity in compromised wounds.⁸

Topical antimicrobial agents

Topical antibiotics and antiseptic agents have a long history in prevention and treatment of skin and wound infections. Antiseptic agents are gaining renewed interest and usage because they have a lower

risk to induce bacterial resistance than antibiotics. Molecular iodine is one of the most potent and broad-spectrum antimicrobial agents.²⁶

Some naturally occurring antimicrobial peptides that provide an endogenous defence mechanism in organisms ranging from bacteria to mammals have proved to be effective in compromised wound therapy.²⁷ Defensins and magainins are examples of such cationic peptides that operate by bonding to, and increasing the permeability of, bacterial membranes, with subsequent cell lysis and death.²⁸ A magainin derivative has been shown to exhibit broad-spectrum antimicrobial activity against more than 2500 Gram-positive and Gram-negative aerobic and anaerobic bacteria from infected ulcers.²⁸ These data suggest that antimicrobial peptides may provide a new strategy in the topical management of compromised wounds in the future.

Dressings

Since the 1960s, maintaining a moist wound environment has been recognized as being optimal for wound healing, and, as a consequence, moisture-retentive dressings, such as hydrocolloids, polyurethane films and foams, are now widely used. However, since a moist wound may contain a nutritious environment, this may also stimulate microbial growth. Infection might, therefore, occur if such conditions are maintained in a wound. In reality, this rarely occurs, and lower infection rates have been reported in wounds under moisture-retentive dressings compared with the infection rate under traditional gauze dressings.²⁹ The increasing availability of moisture-retentive dressings that contain antimicrobial agents may help to reduce infection and provide a new generation of products designed to optimize conditions for wound healing.

Specific compromised wounds

Non-healing wounds in irradiated tissue

Maxillofacial surgeons should be aware of the negative effects of oncologic therapy, especially in the oral cavity, to avoid serious problems. Radiotherapy is a well established treatment for advanced head and neck cancer. Early and late oral complications may occur in patients submitted to radiotherapy. Among the problems seen, the most frequent are: mucositis of the oral mucosa, xerostomia, trismus of the temporomandibular joint, increased caries, periodontitis, subcutaneous fibrosis, and osteoradionecrosis (ORN).³⁰⁻³² It is important for the surgeon to know the radiation dose delivered and the extent of the radiation fields, to avoid, or at least minimize, the risk for severe complications such as ORN when performing surgery in irradiated tissues.

Irradiated tissues have a decreased repair and remodeling ability after radiotherapy. The changes induced after radiotherapy are believed to be due to reduced cell turnover leading to reduced blood supply and reduced ability for bone repair.³³ Increased loss of attachment in the periodontium of teeth exposed to high-dose radiotherapy has been detected.^{34,35} These alterations may contribute to increased risk for infections, tooth loss, difficult-to-heal wounds, and ORN.

Osteoradionecrosis

ORN is perhaps the most feared late complication of irradiation, affecting the mandible more often than the other bones of the head and neck. It can occur as a complication after external beam radiotherapy, after brachytherapy, and as a result of either primary radiotherapy or adjuvant treatment. The exact definition of ORN has been a topic of debate in the literature, but, in general, it is a condition in which irradiated bone becomes devitalized and exposed through the overlying skin or mucosa, persisting without healing for more than 3–6 months.³⁶ This may progress to a pathological fracture, infection of soft tissues, and the formation of cutaneous fistulas, combined with severe and constant pain. The time taken to develop ORN can vary from 3 months to more than 15 years after radiotherapy. Dental extractions, surgery, or trauma frequently precede the onset of ORN, and it is probably related to impaired wound healing rather than infection, though secondary infection may be present. Factors that affect the development of ORN include primary site of cancer, proximity of tumour to bone, dentition, and type of cancer treatment and the radiotherapy dose. In addition, host factors such as age, sex, general health, cardiovascular disease, nutritional status, and continued tobacco and alcohol use may influence the onset of the disease.^{37–40}

Originally, the three factors thought to contribute to the development of ORN were irradiation, trauma, and infection.⁴¹ In the 1980s, Marx³⁶ described the first widely accepted theory of the pathophysiology of ORN. He proposed that irradiation caused an endarteritis that resulted in tissue hypoxia, hypocellularity, and hypovascularity, which in turn caused tissue breakdown and development of a chronic non-healing wound. Also, radiotherapy reduces the growth and function of bone marrow, affects periosteal and endosteal cells, and may reduce collagen production.⁴² It is now thought that osteoclasts suffer irradiation effects earlier than vascular alterations and that suppression of bone turnover via osteoclasia is another etiologic factor of importance.⁴³ It has recently been proposed that ORN arises from what is thought to be a fibroatrophic process.⁴⁴ The vascular damage concept is supposed to relate to endothelial cell reactions to radiotherapy, which range from apoptosis to permanent phenotypic changes. These vascular dysfunc-

tions help to generate the initial prefibrotic phase. A second but related theory is that of fibroblastic stromal change, which occurs as a result of reactive oxygen species' deregulation of fibroblast proliferation and metabolism.⁴⁴

Historically, the treatment of ORN has relied on a combination of conservative measures (antibiotics, debridement, and irrigation), surgical resection (sequestrectomy, marginal mandibulectomy or segmental mandibulectomy, with or without reconstruction), and HBOT. Roughly half of the patients ultimately require surgical resection of the mandible.⁴⁵ All necrotic bone should be removed, and, ideally, blood supply to the tissue be optimized. It has been proposed that the time interval between the completion of radiotherapy and the onset of ORN helps to dictate aggressiveness of surgical management,⁴⁶ but the amount of bone to be resected is a clinical decision and is based on the presence of bleeding edges of the remaining bone. For advanced stages of ORN (pathologic fractures, extraoral fistulas) segmental mandibular resection with free vascularized bone grafting has become the standard of care.

An adjunctive conservative measure that has been used since the 1960s is HBOT.⁴⁷ Using Marx's theory that ORN is a result of hypoxia, hypocellularity, and hypovascularity, HBOT is an attractive option. It increases oxygen supply in hypoxic tissue, stimulating fibroblast proliferation and angiogenesis.⁴⁸ Furthermore it stimulates collagen formation and can be bactericidal or bacteriostatic to many species.⁴⁷ For many years, the use of HBOT has been advocated for preoperative and postoperative treatment in high-risk patients undergoing tooth extractions and other surgical interventions. The beneficial effect of HBOT can be seen in the improved microvasculature of the bone.⁴⁹ In smaller lesions, it has been used in conjunction with conservative measures in an effort to avoid surgical resection of the mandible.^{50,51}

Osseointegration in irradiated tissues

Whether osseointegrated implant failures are increased after radiotherapy or not has been the subject of debate; the need for precautions such as HBOT therapy has also been debated.^{52,53} Increased knowledge today shows that a number of factors affect implant survival in irradiated bone. These include radiotherapy given before or after implant installation.^{54–56} Combined pre- and postoperative irradiation is particularly damaging to implant integration.⁵⁷ Factors that affect implant survival include irradiation dose and fractionation, chemotherapy, time from radiotherapy to implant surgery, but other factors such as fixture length and prosthetic retention also affect the results; the length of the follow-up is also relevant.⁵⁶ Despite the fact that implant survival might be affected by radiotherapy, the benefits that

the patient can gain from receiving osseointegrated implants is so high that it is often recommended. However, it is also stressed that cancer patients who are to receive osseointegrated implants should be treated at institutions well used to handling cancer patients. The risk for induction of osteoradionecrosis is always present, and it is of the utmost importance that such side effects are avoided. Adjunctive use of HBOT can reduce that risk and also improve survival of these implants.⁵⁸

Compromised skin grafts and flaps

Most modern reconstructive surgical procedures show good outcomes and no specific precautions are generally needed in normal, uncompromised skin grafts or flaps. However, in previously irradiated cancer patients, the risk for complications is significantly higher.⁵⁹ There are three distinct areas where adjunctive HBOT may be of significant value in the management of plastic surgical problems: preparation for grafting in irradiated tissue, salvage of compromised flaps and grafts, and reimplantation of facial structures.

Acutely compromised skin grafts and flaps benefit significantly from HBOT. Flap mottling after surgery is an immediate emergency indication for HBOT. In compromised flaps, HBOT can enhance flap survival and extend the margins of tissue salvage while also reducing the risk of sepsis. This has been confirmed in animals and several clinical studies. A critical review of HBOT and its application in different types of flap failure has been summarized by Zamboni *et al.*⁶⁰ Although different types of flaps and grafts have been analyzed in these studies and each flap problem is unique, the final determinant of flap necrosis was considered to be tissue hypoxia.

Old age – osteoporosis

Osteoporosis is a major health problem in societies with an ageing population. It is characterized by compromised bone strength that predisposes patients for an increased risk of fracture. Osteoporotic bone differs from normal bone in mineral composition, bone mineral content, and crystallinity.⁶¹ Poor bone quality in patients with osteoporosis presents the surgeon with difficult treatment decisions, i.e. regarding installation of osseointegrated implants. Increased failures of osseointegrated implants in older patients have been reported. Implant failures were correlated to a lower blood flow in the osteoporotic bone.⁶² When treating patients with jaw fractures, complications and slow fracture healing may occur. Fracture healing is a complex process, involving a well organized process that may be affected by both biological factors, such as age and osteoporosis, and mechanical factors, such as stability of the osteosynthesis.

Much effort has been expended to develop therapies that preserve bone mass and thus decrease frac-

ture risk.⁶³ Both manipulation of the local fracture environment, in terms of application of growth factors, scaffolds, and mesenchymal cells, and systemic administration of agents promoting bone formation and bone strength have been considered.⁶⁴ However, at present no general recommendations for the use of these treatments can be given.

Diabetes mellitus

Worldwide prevalence of diabetes is high (20% of individuals over 65 years), and is increasing.⁶⁵ Type 2 diabetes represents about 90% of the total diabetes cases. Diabetic patients have sometimes been denied maxillofacial surgical treatments such as osseointegrated implant installation, because of their increased susceptibility to infection, delayed wound healing, and microvascular complications.^{66,67} Diabetes control is critical for reducing complications of the disease. Patients with glucose fluctuations may be at more risk for complications.⁶⁸ For diabetic patients undergoing major surgery, it has been well established that absolute control of glucose plasma level by intensive insulin therapy in the perioperative period reduces the postoperative complications, i.e. deep wound infection and surgical site infection.^{69,70}

Using a similar scheme for strict control of plasma glucose, it has been shown that conventional and advanced implant surgeries, including lateral window sinus elevation, immediate loading, and guided bone regeneration can be performed without serious side-effects, and with surgical results comparable to those in non-diabetic patients.⁷¹ Thus strict control of plasma glucose in diabetic patients is recommended.

Drugs – bisphosphonates

Recently, oral and maxillofacial surgeons were the first clinicians to recognize and report cases of non-healing, exposed necrotic bone in the maxillofacial region in patients treated with intravenous (and more recently oral) bisphosphonates.⁷²⁻⁷⁴ The potential mechanism by which bisphosphonates are associated with development of osteonecrosis is still a matter of debate. Marx *et al.*⁷⁵ suspected the mechanism of osteonecrosis involved bisphosphonate-related apoptosis of osteoclasts as well as antiangiogenic effect. The rich vascularization of the jaws is believed to render them more susceptible to the deposition of bisphosphonates than other bones. Bone remodeling of the jaws can then be depressed, leading to spontaneous breakdown or poor healing after tooth extractions. Several consensus papers have been published that make recommendations for handling of bisphosphonate-induced osteonecrosis.^{76,77} The guidelines recommend today (2010) that unnecessary surgery be avoided as long as possible. If surgery must be undertaken, areas of necrotic bone should be removed and, if necessary, fractures stabilized by use of reconstruction plates. Any surgery to cure bisphosphonate-

induced osteonecrosis should only be performed in patients with extensive disease. Reconstruction by vascularized and non-vascularized bone transfer should be avoided. Further research is needed to better understand the pathogenesis of this disease, and better options for treatment are also needed.

Chapter 12

Extraction of Teeth

Adel Al-Asfour and Sanjiv Kanagaraja

Extraction is probably the most frequent oral surgical procedure worldwide and can be one of the simplest procedures as well as one of the most challenging technically. This is also a procedure that has profound effects on oral health status, often requiring restorative procedures to replace the missing tooth. It has also a psychological impact on the patient, both due to the fact that the patient will be losing a tooth/teeth, and the associations the patient will have with such a procedure. Extraction of teeth incorporates basic principles from physics, mechanics, and surgery, and the clinician should fully understand and master the techniques of extraction. A correct approach and performance of an extraction should lead to a tooth being gently lifted out of its socket without excessive trauma to surrounding soft and hard tissue and should prevent complications. In some situations, however, simple extraction is not possible and a surgical extraction must be carried out. This chapter gives an overview of the art of tooth extraction.

Medical evaluation

As with many surgical procedures described in this book the medical status of the patient is crucial in the presurgical evaluation. Furthermore, the mental status of the patient is important since extraction requires the patient to be fully cooperative. The reader is referred to Chapter 1 for detailed information regarding patient evaluation.

Indications for extraction

The common position of modern dentistry is that all teeth should be treated and maintained in the oral cavity as long as possible, provided they fulfil functional and even esthetic criteria. However, it is sometimes inevitable that teeth have to be removed for various reasons.^{1,2} General indications for extractions will be discussed below, but the reader should be aware that the decision to extract has to be made individually for each case, and that recommendations are not absolute.

Caries

Severe caries and an extensive loss of tooth substance that will not permit restorative procedures is perhaps the most common reason why teeth are extracted.

The decision to extract a carious tooth instead of trying restorative procedures is something to be made by the surgeon and patient together.

Periodontal disease

Another common reason for tooth extraction is periodontal disease. Severe bone loss and irreversible tooth hypermobility is an indication for extraction (Fig. 12.1). However, bone regeneration techniques exist today and the dentist should consider this alternative before the decision to extract. The severity of periodontal disease, long-term prognosis, and even cost/benefit aspects should be considered in the decision-making process.

Pulp disease

The presence of irreversible pulpitis, pulp necrosis or internal resorption of the root canal where endodontic procedures are not possible are other indications for tooth extraction. This could be because of obliterated root canals, canals that are not accessible due to root anatomy, failure of endodontic therapy or when patient chooses not to undergo such treatment.

Pathologic lesions surrounding teeth

The most common pathologic lesion associated with teeth is apical or juxtaradicular periodontitis. If endodontic procedures are not possible, then extraction should be considered. Besides, if teeth compromise the surgical treatment of other pathologic lesions found in the tissues surrounding them, then extraction should be considered, e.g. in the treatment of osteomyelitis of the jaw.

Before radiation therapy

Careful consideration should be given to patients who are to undergo radiation therapy due to tumors

Fig. 12.1 Severe periodontal disease has led to extensive bone loss around 45 which is hypermobile and due to be extracted. Extraction in this case is easy.

in the head and neck region. Teeth associated with pathologic conditions such as periapical periodontitis should be considered either for swift endodontic procedures or extraction. Extractions should preferably be carried out before the start of the radiation therapy. A radical approach before radiation is recommended to avoid later complications in the irradiated bone. See Chapter 35 for more details.

Crown and root fractures

Crown, crown-root, and root fractures after trauma can often be successfully treated and extraction avoided, see Chapter 39. However, there are other situations where fractures of the crown and root do not allow successful restorative therapy (Fig. 12.2). In these cases extraction is the only alternative.

Teeth in bone fracture lines

Sometimes teeth in the line of a jaw fracture should be considered for extraction in order to prevent infection. Tooth luxation can almost always be treated by repositioning and fixation, but where there is severe luxation of teeth associated with complex jaw fractures, where teeth are in the line of the fractures and interfering with the repositioning, these teeth should be extracted (Fig. 12.3).

Malposition of teeth

Malposition of teeth in itself is not an indication for extraction. However, malposition associated with other conditions such as trauma to soft tissue or blockage of eruption of adjacent teeth is an indication for extraction. Where there is elongation of teeth due to the missing antagonist and where prosthetic rehabilitation is considered in the oppos-

Fig. 12.2 Crown fracture of 36 leaving two delicate roots. These roots could be fragile and likely to fracture when extraction is attempted. Surgical removal of these roots should be considered.

Fig. 12.3 Tooth 48 which is root fractured and is located in the line of a mandibular fracture should be extracted. Tooth 33 is also in the line of a fracture but can be preserved if it does not interfere with repositioning of the bone fragment.

ing jaw, the elongated tooth may be considered for extraction (Fig. 12.4).

Impacted teeth

Some impacted teeth do not reach functional occlusion, often because of lack of space. These teeth should be investigated and considered for extraction if they interfere with adjacent teeth or present a potential for the development of pathology in the future. These could include the risk for root resorption of adjacent teeth, loss of bone around adjacent roots or development of other pathologic conditions such as cysts. Impacted third molars are the most common teeth considered for extraction. For more details regarding strategies for third molar extraction see Chapter 14.

Fig. 12.4 Cone-beam computed tomography (CT) scan showing malposition of the upper left third molar blocking the eruption of the second maxillary molar.

Supernumerary teeth

Supernumerary teeth that are potential sources for future pathology should be removed (Fig. 12.5). The rules for impacted teeth apply to supernumerary teeth, which are often impacted. However, supernumerary teeth without pathology do not have to be routinely removed.

Orthodontic indications

Extraction of teeth is sometimes required to create space in order to carry out planned orthodontic treatment. The decision on which tooth/teeth are to be extracted is made by the orthodontist.

Before prosthetic extractions

Before prosthetic reconstructions it is sometimes necessary to extract teeth. Teeth could interfere with

Fig. 12.5 Supernumerary tooth in the first molar region. This tooth will have to be followed radiologically and should be removed if any signs of pathology, such as progressive root resorption of the first molar, is suspected.

the proper placement of a fixed or removable prosthetic appliance and should be extracted. In the case of rehabilitation of a jaw with implants where there are one or two incisors remaining that have a dubious prognosis, it may sometimes be better to extract the remaining teeth and perform a full arch implant-supported reconstruction.

Before surgical extractions

Sometimes teeth have to be removed prior to other surgical procedures. The most common indication in this regard is the removal of impacted molars prior to LeFort-I or sagittal split osteotomies. This is done if the teeth lie in the line of the planned osteotomies or increase the risk for other complications such as undesired fractures.

Other reasons for extraction

There are other situations where extraction may be chosen, even when the extraction may be on doubtful indications. In these situations it is especially important to discuss alternative treatment and inform the patient preoperatively so the surgeon and patient agree on the choice of treatment. Extractions can be performed due to economic reasons. Patients might choose to extract a tooth rather than incur the costs of, for example, having endodontic treatment or a more expensive restorative procedure. Extractions can also be performed due to esthetic reasons. For example, the patient could choose to extract an upper malformed lateral incisor and have it replaced with an implant. Further, a patient could choose to extract protrusive teeth in the upper front and have them replaced by an implant-supported prosthesis as an alternative to undergoing orthodontic or orthognathic surgical correction. Malformed or severely discolored teeth could also be considered for extraction due to esthetic reasons where the patients choose extraction and prosthetic reconstruction over other procedures such as veneers and crowns. Teeth could sometimes also be extracted due to difficulty in maintaining adequate oral hygiene. Most commonly, the third molars are extracted due to inadequate oral hygiene and the recurrence of pericoronitis.

Contraindications for extraction

The decision to extract a tooth cannot be made entirely based on the status of the tooth and immediate surrounding tissue. The dentist should also consider the contraindications to extracting the tooth, for example with consideration of the patient's general health, which might overwhelm the indications for extraction.¹⁻³ In such a case the decision to extract is revised and the tooth left in place. Contraindications for extractions are for the most part relative and could be altered by the clinician implementing other treatments.³ When the contraindication is no longer

decisive, the previously planned extraction can be carried out.

Systemic contraindications

These constitute all general health factors and mental factors which have influence on the patient's ability to withstand the surgical procedure. Severe dental anxiety is a relative contraindication to extraction unless the procedure is planned under general anesthesia.

Patients with hemophilia or other coagulopathies should first have their disorders controlled before extraction. In general, most uncontrolled metabolic diseases such as diabetes constitute a contraindication until they are brought under control. Similarly, patients with severe uncontrolled hypertension and cardiac diseases should be treated for these conditions first before extractions are carried out. Ongoing radio- and/or chemotherapy is also a relative contraindication. In all cases, one should be aware of the medications patients are on or have had, especially those drugs that affect the immune system, delay or impair the healing process, or could interact with medication administered to manage an extraction. One should pay extra attention to patients on anticoagulant drugs, cancer medication, glucocorticoids and immunosuppressants. For a more detailed overview of medical contraindications see Chapter 3.

Local contraindications

The most common local contraindication is an ongoing acute inflammatory or infectious process. The acute infection/inflammation should first be treated before proceeding with the extraction, depending on the location of the acute process. Extraction of a third lower molar during an ongoing acute pericoronitis could lead to a life-threatening postoperative infection. However, there are also situations where an acute abscess is best drained by extraction of the tooth even in an acute phase. An acute infectious process caused by pulpal disease is resolved most quickly by extraction of the tooth. Therefore an acute infectious and inflammatory process should not be considered as an absolute contraindication for extraction. The dentist should, however, bear in mind that there could be other problems, such as severe pain, swelling, reduced mouth opening, and anxiety, which could make extractions associated with other acute conditions suboptimal. In such cases extractions should be deferred until the acute symptoms have subsided.

One of the most important contraindications to extraction is radiation therapy, past and present, involving the jaws. Delayed healing, dehiscence, and necrosis of the bone are often complications due to extractions performed in irradiated bone. Some cancer medications can also cause necrosis of the jaws

after extractions. For more details refer to Chapter 35. Finally, teeth within the area of a tumor, especially if it is malignant, should not be removed.

Clinical evaluation of teeth before extraction

The condition of the crown is assessed in order to evaluate if there is a high risk for fracture of the crown during extraction, which would thereby complicate the procedure. Surgical extraction of teeth with missing crowns or severe caries may be considered. Other factors to consider are tooth/root mobility and access to perform the extraction. Again, pathology of the pulp and surrounding soft tissues should be assessed so that the extraction can be carried out with a minimum of discomfort to the patient. Severe gingivitis or pulpitis, for example, could result in excessive bleeding or inadequate effect of local anaesthesia respectively, which could add to patient discomfort. The clinical evaluation of the tooth to be removed is done in conjunction with a radiographic assessment.

Preoperative radiographic assessment

It is imperative that a thorough radiographic examination be done prior to extraction of teeth. This helps the dentist to evaluate the degree of difficulty of extraction by assessing root anatomy, presence of pathology in the root or surrounding bone, vital structures and relation to other roots, and other factors such as ankylosis or hypercementosis of the root (Fig. 12.6). The most common and adequate radiograph is a good quality intraoral periapical radiograph. Other techniques such as panoramic radiographs, scanograms, and cone-beam radiological techniques are more valuable in the mapping of impacted teeth. For details of imaging techniques see Chapter 2.

In the maxilla, the proximity of the roots of the molars to the sinus should be assessed. In some cases the sinus membrane can rupture during extraction of maxillary molars causing an oroantral communication (Fig. 12.7). In the mandible, the position of the mandibular canal should be noted, especially in rela-

Fig. 12.6 (a) Hypercementosis of the mesial root of the first lower left molar would prompt surgical extraction of this tooth. Closed extraction in this case is impossible. The second molar has a large restoration, and the tooth could be fragile leading to fracture. The option of surgical extraction should be considered. (b) The extent of external root resorption makes extraction of the canine almost impossible due to the risk for fracture. Surgical extraction should be considered. (c) The root configuration of the second lower right molar makes it impossible to remove this tooth without a surgical procedure. (d) The lower first right molar has slender roots that taper towards each other apically. Besides, the cervical portion of the mesial root is narrower than the apical part. This will make extraction difficult and surgical extraction will have to be considered.

Fig. 12.7 (a) Note the proximity of the sinus membrane to 15. The infection around the apex of 15 can lead to destruction of the lower sinus wall and cause an oroantral communication when 15 is extracted. (b) Large maxillary sinus that extends over the apices of the molars with a risk for oroantral communication during extraction of these teeth. (c) Severe caries and loss of tooth substance will make extraction of 26 difficult. The maxillary sinus is in close relation to the apices which have apical periodontitis. This increases the risk for a rupture of the sinus membrane when extraction is attempted.

tion to third molars (Fig. 12.8). The position of the mental foramen should be noted in cases where a flap has to be raised in order to remove the premolars (Fig. 12.9).

Control of anxiety and pain

For a successful dental extraction, control of the patient's anxiety and pain is essential. Most patients have anxiety when undergoing an extraction procedure. Local anesthesia must be sufficient to eliminate pain and sensation from the involved tissues.

Sedation

Although pain associated with extractions is managed effectively through the administration of local anesthesia, patients are anxious because of the fear of pain. Anxiety control may vary from the surgeon simply showing concern and empathy for the anxious patient to the use of oral or parenteral drugs for sedation of the very anxious patients. In some patients general anesthesia has to be used to enable treatment. For further information regarding sedation and general anesthesia the reader is referred to Chapter 6.

Local anesthesia

Surgeons who are going to extract a tooth must have knowledge of the anatomy and especially the inner-

Fig. 12.8 (a) Scanogram showing the relation of the mandibular canal with respect to the apices of 37 and 38. Root anatomy makes it highly likely that the third molar would require a surgical extraction. The position of the mandibular canal must be determined before surgical extraction. (b, c) The distally angulated third molar and configuration of the root make an extraction avoiding a root fracture very difficult. Note the position of the mandibular canal in close proximity to the roots.

variations of teeth and surrounding soft and hard tissue. The surgeon must also be familiar with the techniques of local anesthesia. Profound local anesthesia results in loss of all pain, temperature, and touch sensations, but it does not anesthetize the proprioceptive fibers. The patient still may therefore feel sensations of

Fig. 12.9 (a) The mental foramen is just inferior to the roots of 45 with the anterior loop of the mental nerve visible. (b) The mental foramen is projected in contact with the apex of 45. The lamina dura of the root can be distinctly followed throughout, and this excludes apical pathology. (c) It is difficult to identify the position of the mental foramen from this single radiograph. Before surgical removal of the second premolar additional radiographs are needed to determine the relation to the mental foramen.

pressure which must be explained to the patient prior to local anesthesia and extraction.

There are various local anesthetics in use. They can be used with or without vasoconstrictor. They differ in their concentration, and duration of anesthesia. Each local anesthetic has a recommended maximum dose to ensure safety of the patient and this must be considered, especially when administered in very old or young patients. For more details regarding local anesthesia see Chapter 5.

Preparation for extraction

The concept of cross-infection control must be adopted during extraction. Patients must be regarded as possible carriers of blood-borne diseases that can be transmitted to the surgical team and the surgeon should practice the universal precautions to prevent injury or transmission of disease to their patients or themselves. Therefore, surgical gloves, surgical masks, and glasses or eyescreens with side shields should be worn by the surgeon even for simple extractions (Figs 12.10–12.12). The surgical team should wear long-sleeved gowns. For the patient, a minimal draping is necessary for performing simple extractions, with a sterile drape placed across the patient's chest. Hair should be ideally be covered both on surgeon and patient. Preoperative mouth-rinse with antiseptic, such as chlorhexidine, is recom-

mended to reduce the number of microorganisms at the surgical site.

Surgeon's position for extraction with forceps

The positions of the patient and surgeon are important for successfully performing extraction. The optimal position is when both patient and surgeon are comfortable (Figs 12.10–12.12). Dental extraction can

Fig. 12.10 Surgeon with proper clinical attire: gloves, mask, cap, and protective eye shield. Patient with sterile drape across the chest and a cap. The surgeon is in a standing position for extracting maxillary anterior teeth.

be performed with the surgeon sitting or standing. Most surgeons prefer the standing position. Regardless of whether the surgeon is sitting or standing, the correct positioning of the surgeon should allow him/her to deliver a controlled force to the patient's tooth through the forceps. The correct position allows the surgeon to provide stability and support and to enable the wrist to be straight with controlled force delivered from the arm and shoulder. The importance of this controlled force during extraction is to prevent any injury following sudden loss of resistance from the fracture of a root. The patient's chair should be tilted backwards. The height of the chair should be such that the patient's mouth is at the surgeon's elbow.

When extracting teeth in the maxilla, the surgeon should stand in front or by the side of the patient. For extraction of the mandibular teeth, the surgeon should approach the patient from behind during extraction of right posterior and anterior teeth. When

Fig. 12.11 Surgeon with proper clinical attire: gloves, mask, cap, and protective eye glasses. Patient with sterile drape across the chest and a cap. The surgeon is in a standing position for an extraction from the maxilla.

Fig. 12.12 Surgeon with proper clinical attire: gloves, mask, cap, and protective eye shield. Patient with sterile drape across the chest and a cap. The surgeon is in a sitting position with the patient lowered as low as possible so the mouth is level with the surgeon's elbow. The surgeon is in a sitting position for an extraction from the mandible.

extracting left posterior mandibular teeth, the surgeon should approach the patient from the front. The mandible can be supported by the surgeon's non-extraction hand. The approach from behind gives the surgeon great visibility of the extraction site and it allows the surgeon to be in a comfortable and stable position.

Principles of simple (closed) extraction

The mechanical principles applied from physics in extractions are the principles of lever, wedge, and rotating wheel and axle, where forces are transformed from long axes of the instruments and the surgeon's arms to deliver a high force in an appropriate direction at the point of application on the teeth and roots.^{1,3}

Extraction of a tooth requires expansion of the alveolar socket and separation of the attachment of the periodontal and attaching gingival soft tissues. For this reason it is important to study the anatomy of the tooth and its root, its periodontal ligament, and oral soft tissue attachment prior to extraction.

Controlled force is delivered with dental elevators and forceps to expand and, in a controlled way, fracture the alveolar socket without fracturing the alveolar process, roots or crown of the tooth. The force delivered must be carefully applied to avoid excessive damage to the supporting structures and adjacent teeth.

The tooth has to follow a certain path upon delivery from its socket. Dental forceps and elevators have been designed to provide a mechanical advantage for the delivery by a controlled force. The instruments used to extract teeth should therefore be properly selected and handled in order to deliver a controlled force in appropriate directions.

To avoid fracture of the tooth the forceps should firmly engage the tooth as apical as possible without

Fig. 12.13 The use of a periosteal elevator for releasing and expansion of gingival tissue before using elevators and forceps for extraction. This creates space for both instruments and minimizes soft tissue injury during extraction.

injuring the adjacent structures. The force delivered during removal while grasping the tooth as apical as possible can lower the center of rotation toward the apices of teeth, minimizing the chance of fracture of crowns or roots.

The first step in extraction is gently expanding the alveolar bone. This is achieved by introducing a dental elevator as a wedge as far apically as possible in the socket at the neck of the tooth to be extracted. Some surgeons prefer to start with gentle reflection of the gingival tissue around the tooth neck with a periosteal elevator to minimize the soft tissue injury and prepare for the beaks of the forceps (Fig. 12.13).

The dental elevator is used for lever transmitting from a long lever arm with moderate force into a short lever arm with high force (Fig. 12.14). A quarter turn moving the dental elevator toward the object tooth causes the alveolus to expand, loosening the periodontal ligaments, and forcing the tooth coronal-

Fig. 12.14 The dental elevator is used as a wedge with the tip being forced into the periodontal space to expand the alveolar bone and force the tooth out of the socket.

Fig. 12.15 The forceps is applied to the crown of a central maxillary incisor. The forceps is placed as far apically as possible so the center of rotation (star) is located as palatally as possible. Continued apical pressure is applied and the incisor is luxated buccally and lingually. Once some mobility is noted, the conical root allows rotational forces to be applied. Buccal, palatal, and rotational forces are used and finally the tooth is lifted out of its socket. The same technique can be used to extract maxillary lateral incisors and canines.

ly. The thumb and forefinger of the non-extracting hand of the dentist should be used to hold the alveolus, with one finger on the buccal and the other finger on the lingual aspects; in this position, the dentist can sense the amount of force being applied and the degree of movement of the object tooth. This maneuver can also protect the surrounding soft tissue and adjacent teeth from inappropriately applied accidental forces (Fig. 12.13).

The appropriate dental forceps can then be applied as far apically as possible by acting as a wedge in the socket. A steady grip must be obtained and luxation pressure is applied in lingual and buccal directions (Figs 12.15–12.17), continuing with gently applied persistent force to expand the alveolus. The center of

Fig. 12.16 The forceps is applied to a maxillary first premolar which has two thin roots. There is a high risk of fracture if careful technique is not applied. The forceps is placed as far apically as possible to move the center of rotation (star) as far apically as possible. The tooth is then luxated carefully buccally to expand the alveolus, and thereafter the tooth is luxated palatally. Rotational force should be avoided in teeth that have more than one root. After the tooth has been luxated it can be lifted out of its socket.

Fig. 12.17 The forceps is applied to a maxillary molar with two buccal and one palatal roots. Three-rooted teeth and root divergence will make the extraction difficult. The initial step is to seat the forceps firmly against the tooth and apply apical force to move the rotational center (star) as far apically as possible. Expansion of the sockets is achieved by careful buccal and palatal luxation. Large initial forces should be avoided and can result in uncontrolled fractures of the roots, buccal bone plate or tuberosity. Forces in buccal and palatal directions will enable bone expansion. After the tooth has been luxated the tooth is then carefully delivered out of the socket and mouth buccally.

rotation should be kept as apical as possible. One-rooted teeth can be rotated after initial luxation (Fig. 12.15). As the tooth gets luxated and loosened, the forceps should be repositioned as far apically as possible, this will increase the efficiency of the forceps, and thus lessen the chance of fracture of the roots.

Most erupted teeth can be extracted by simple extraction using the methods described.³ However it takes some time and experience to get the right feeling for luxation without fracturing roots. As the surgeon gains experience, his or her efficiency will improve, and the surgeon will also develop a sense for teeth that may present problems in their removal. If the extraction is difficult, a decision should be made early to surgically remove the tooth rather than apply excessive force. This is important, in that excessive force increases discomfort and anxiety of the patient, the risk for root and crown fractures, and the time for extraction.

Surgical (open) extraction of teeth or roots

Teeth that cannot be extracted by simple extraction require extraction by the use of a surgical flap. As a general rule, surgeons should consider performing an elective surgical extraction when they perceive a possible need for excessive force to extract a tooth. The term *excessive* means that the force will probably result in a fracture of bone, tooth root, or both. This will lead to an additional surgery and/or increase surgery time which can cause undue morbidity. The following are examples of situations in which closed extraction may require excessive force.¹⁻³ Surgical extractions for other indications are covered in Chapters 13–15.

1. Failure to remove a tooth with forceps or closed extraction. Instead of applying a force that may be not controlled, the surgeon should simply reflect a soft tissue flap, remove some bone, section the tooth or roots, and extract the tooth in sections.
2. Presence of thick dense bone, particularly bucco-cortical bone as assessed preoperatively. Surgical extraction should be considered. The extraction of most teeth depends on the expansion of the bucco-cortical plate. If this bone is thick and dense, adequate expansion is less likely to occur, and fracture of the root may be more likely. Dense bone in an older patient warrants even more caution.
3. Presence of short clinical crowns with signs of severe attrition as a result of bruxism or habitual grinding. It is likely that the teeth are surrounded by dense heavy bone. The surgeon should exercise extreme caution if removal of such teeth is attempted with a closed technique. An open

technique usually results in a quicker, easier extraction.

4. Hypercementosis. This is a condition where cementum has continued to be deposited on the tooth and has formed a large bulbous root that is difficult to remove through the available tooth socket opening. Great force used to expand the bone may result in fracture of the tooth or bucco-cortical bone and in a more difficult extraction procedure (Fig. 12.6a).
5. Teeth with long and divergent roots, especially the maxillary first molars or roots that have severe dilacerations or hooks, are also difficult to remove without fracturing one or more roots. By reflecting a soft tissue flap and sectioning the roots with a bur, a more controlled and planned extraction can be performed, with less morbidity (Fig. 12.6c, d).
6. Presence of large pneumatized maxillary sinus with the roots of maxillary molars extending into the sinus especially in the case of isolated molars (Fig. 12.7b). Extraction may result in removal of a portion of sinus floor with the tooth leading to an annoying complication known as oroantral communication. If the roots are divergent, such situation is even more likely to occur.
7. Teeth with extensive caries, root caries, or that have large amalgam restorations are candidates for surgical extraction (Figs 12.7c, 12.18). Although the tooth is grasped primarily by the root, a portion of the force is applied to the crown. Such pressures can crush and shatter the crowns of teeth with extensive caries or large restorations. Planned open extraction will result in quicker and easier extraction. Teeth with crowns already lost secondary to extensive caries, and present in the mouth as retained roots, can be considered candidates for surgical extraction.
8. Deciduous teeth occasionally present problems for the surgeon and should not be underestimated. The prime consideration in the removal of

Fig. 12.18 Preoperative periapical radiograph showing severe caries in a second mandibular molar to be extracted. There is also evidence of a large amalgam filling on the first molar. Because of the high risk of fracture of crowns and filling a surgical extraction may be preferred.

deciduous teeth is to avoid injury to the developing permanent dentition. The enamel of the deciduous crowns is more brittle, and the roots are much flatter and more convex. Because the deciduous roots have already undergone resorption, seating the forceps far apically beneath the deciduous tooth may accidentally damage the developing permanent tooth. Primary teeth, especially the mandibular molars, may be submerged or ankylosed, so they should be percussed before extraction. If ankylosis is suspected, the tooth's removal should be reassessed. Radiographic changes include loss of evidence of a periodontal ligament space and apparent fusion of the bone and the tooth structure. Clinically, there is absence of mobility and a characteristic solid tone on percussion with a metal dental mirror handle. If extraction is necessary owing to infection or obstruction of an erupting permanent tooth, it is best done by a surgical procedure.

9. Erupted mandibular third molars with limited access. Although such teeth are not technically impacted, a forceps extraction is difficult due to difficulty of using the forceps properly and the presence of thick alveolar bone. Planned surgical extraction is performed by raising a soft tissue flap, and judicious removal of the buccal bone using fissure bur and surgical handpiece with copious saline irrigation to create a buccal trough to provide access for efficient instrumentation and atraumatic removal of the tooth. Surgical removal of third molars is covered in Chapter 14.
10. Endodontically treated teeth. Despite good pre-operative planning, occasionally tooth and roots will fracture during extractions. This is especially true for teeth previously treated with endodontic therapy, which often results in teeth that are brittle and may split during extraction.

Technique for surgical extraction

Surgical extractions should be carried out under high-standard aseptic conditions with the surgeon and assistant scrubbing up, wearing sterile gloves, caps, and masks, and using sterile instruments. The patient should be draped. High-speed air turbines should be avoided because of the risk for development of emphysema once a flap has been raised. Irrigation by sterile saline should be carried out when bone and teeth are cut by bur.

The flaps used with tooth extractions are envelope or sulcular flaps, which are developed along the cervical necks of the teeth.¹⁻³ If extended along the gingival margin they usually provide sufficient access to perform the necessary extraction surgery. It is best to extend this type of flap at least a minimum of one to two teeth both mesially and distally of the object tooth (Fig. 12.19). Another flap used is a modification of the envelope flap, which requires a releasing inci-

sion in either the mesial or distal end of the incision, forming a three-corner flap. Occasionally, both ends of the flap are released forming a four-corner flap.

Bone is removed by rongeur or by a surgical bur to provide access to the tooth which can be removed atraumatically in a more controlled manner. The buccal bone is usually removed and the tooth delivered from buccal aspect. Bone removal varies with the practitioner's personal experience and preference. Bone to be removed should be limited and minimized to preserve the alveolus. This has become important since the widespread use of dental implants requiring sufficient bone volume.

A straight dental elevator is used to expand the periodontal ligament space. The elevator is used as a wedge, pushing it apically to expand the periodontal space and thus displacing the tooth out of the socket. It is important in this case to use the dental elevator carefully by applying a finger rest using the index finger to control the amount of force delivered during removal of the tooth and to prevent slipping of the elevator to avoid unnecessary trauma to soft tissues (Fig. 12.19).

Teeth with two roots, e.g. mandibular molars, can be either sectioned into two halves and then removed similarly to two premolars (Fig. 12.20). In situations where the crown is missing, it is easier to separate the roots and remove them individually (Fig. 12.21).

In cases where the tooth is surrounded by thick cortical bone, bone removal is essential and important for atraumatic surgical extraction. Again a suitable surgical flap is reflected and a bone-cutting bur in a surgical handpiece is used with copious saline irrigation to remove at least one half or two thirds of the buccal bone covering the tooth root in the vertical dimension and about the whole mesio-distal dimension of the tooth in the horizontal dimension. The

Fig. 12.19 Surgical removal of a single root after reflecting a flap. A small straight elevator can be carefully inserted into the periodontal ligament space to expand the alveolus and force the root out of its socket, using the elevator as a wedge. Note the finger support on the adjacent tooth to prevent slipping of the elevator causing unnecessary injuries.

Fig. 12.20 Surgical extraction of a mandibular molar by separating the roots at the cervical level, followed by removal of the roots individually.

tooth can be then easily removed with an elevator or forceps in a buccal direction. Sometimes it might still be difficult to remove the tooth even after removal of bone. If the tooth is quite solid in the bone, a purchase point can be cut in the tooth root and a suitable elevator, e.g. a Cryer elevator, is placed into the purchase point to elevate the tooth out of the socket.

A maxillary molar is removed by separating the crown from the roots and then the tooth is sectioned at the trifurcation area to separate the roots from each other and elevate them out individually. Care must be practiced when using the elevator not to use too much force to push the roots into the adjacent maxillary sinus and to prevent slippage of the elevator injuring the soft tissues (Fig. 12.21).

It is a good practice for a surgeon to inspect the extracted tooth or root and make sure it is removed entirely. This is very important when tooth sectioning is involved. All extracted pieces should be assembled at the end of the procedure and inspected to make sure that the whole tooth or root is removed successfully. A smooth tooth apex on digital palpation also confirms a complete tooth removal.

In all surgical extractions, the base of the flap should be thoroughly irrigated with saline solution and the extraction socket should also be irrigated, especially when contaminated and when there are fragments of restorations or tooth present. Large sharp buccal bony edges should be removed with ronguers and then smoothed with a bone file. The flap is then adapted and sutured.

Postextraction care and instructions

Regardless if a tooth is removed by a closed or open surgical method, the patient should receive postoperative instructions necessary to provide proper care. These instructions should be given verbally and in writing, allowing the patient to take them home.

Fig. 12.21 Surgical removal of maxillary molar roots by elevator after root sectioning. The palatal root has been removed and the buccal roots are separated by an elevator before removal.

The patient and/or patient's guardian should be given the opportunity to ask any questions. After a tooth has been extracted, no debridement or curettage of the socket is necessary unless there is a pathologic process seen on a radiograph preoperatively. Obvious debris, such as tooth fragments, amalgam or calculus, may be present in the tooth socket after extraction and should be carefully removed with a curette or suction. Too vigorous curettage of the socket may lead to additional injury and may delay healing.

Gentle digital pressure with the index finger and thumb should be applied to the bucco-lingual walls of the extraction socket to compress the usually expanded bucco-lingual plates after extraction to restore the original crest dimension. The overlying mucosa should then be palpated to check for any sharp bony edges or projections. If any are present, the mucosa and underlying periosteum should be reflected and sharp bony edges smoothed with a bone file.

Postoperative instructions should include a method of applying direct pressure for initial control of hemorrhage. A moist 2×2 cm gauze should be applied directly over the extraction socket and the patient is instructed to bite down on the gauze for at least 30 minutes without interruption. It is important to place the gauze directly over the extraction site in the space occupied by the crown of the extracted tooth and not over the occlusal table of teeth to ensure that the pressure is correctly transmitted over the socket to achieve hemostasis. The patient should be informed that there may normally be slight postoperative bleeding during the first few hours; some oozing from the wound, which results in a red tinge to the saliva, can be expected for the first 24 hours following the extraction. The patient should be given extra gauze to take home and maintain pressure for another 30 minutes if bleeding resumes. If it is difficult for the patient to stop the bleeding, the patient should contact the surgeon.

The patient should be instructed to stay on a specific postextraction diet. A high-calorie, high-volume liquid diet is best for the first 12–24 hours. The patient must have adequate intake of fluid during the first 24 hours. The fluid can be juices, milk, water, or any other beverage. The patient should be instructed not to use a sucking straw; otherwise he or she will cause negative pressure that might lead to bleeding episodes. The diet should be soft and cool. Cool and cold foods help keep the local area comfortable. Hot and solid foods tend to cause local trauma and/or initiate bleeding episodes.

As with other surgeries the postoperative course also varies with patients, depending on expectations and earlier experience. Mild to moderate postoperative pain is best managed by the use of over-the-counter analgesics, e.g. non-steroidal anti-inflammatory analgesics such as ibuprofen, aspirin, or acetaminophen. A combination of non-narcotics

and narcotic analgesic drugs might be necessary for postoperative pain following extensive surgical manipulation. Whatever drug is chosen, it is important that the patient is instructed to start the pain medication before the effects of the local anesthetic have ended.

The written instruction sheet should contain a telephone number or any emergency number for the patient to contact if he or she has any question or should any complication arise.

Chapter 13

Current Concepts and Strategies for Third Molar Removal

Leif Lysell

Surgical removal of third molars is controversial and various strategies for indications for surgical removal are applied around the world. This chapter gives an overview of current knowledge of the natural history of impacted third molars and the current indications and strategies for third molar removal, and the appropriateness of prophylactic third molar removal is discussed. Public health aspects on third molar surgery are included and relevant aspects on judgement analysis and clinical decision making based on evidence are presented to elucidate when to remove and when not to remove third molars.

Introduction

The surgical removal of third molars has been, and still is, the most frequent operation performed by oral and maxillofacial surgeons both in private practice and in hospital settings. It has not always been a routine, safe procedure with a generally predictable outcome. In the first half of the 20th century, especially before antibiotics became available to the dental profession, severe side-effects of the operation were well recognized by the practitioners, and surgery was often delayed until evident symptoms and pathology

had developed. The second half of the 20th century marked a rapid rise in third molar surgery. This was the effect of a considerable development in technology and pharmacotherapeutics. Development of more efficient rotary cutting instruments, panoramic radiography, improved local anesthesia, outpatient general anesthesia, new chemotherapeutic agents and agents for conscious sedation, together simplified and made third molar removals a considerably safer procedure.¹

Another factor that influenced the practice of oral surgery was the growing interest in preventive dentistry that developed during the 1950s and 1960s. In a major paper on preventive oral surgery,² a “wait and see” attitude towards the asymptomatic impacted third molar was rejected. It was stated that “*current thinking advocates the taking of roentgenograms at the time teeth should normally erupt and, if they are found to be hopelessly impacted and cannot possibly erupt into the mouth and become serviceable teeth, they should be prophylactically removed at this time*”. This approach to the third molar problem was almost universally accepted during the second half of the 20th century and is still the prevailing opinion in a currently used textbook in oral and maxillofacial surgery.³

This concept of prophylactic third molar removal has, however, been questioned by some researchers in the last 20 years.^{4–7} As will be reviewed later, this discussion of prophylactic third molar surgery has been stimulated by research in medical decision making, public health analysis, cost-effectiveness studies and by incorporating patient preferences in decision making. It is well known in the practice of medicine that there is a geographical and cultural variation in diagnosis and treatment⁸ and this variation can obviously also be expected in the management of the third molar problem. This can be explained by a variation in education, treatment traditions, patients’ expectations, cultural variation to risk perception and the supply of expert providers of dentoalveolar surgery.

The aim of this chapter is to survey the current knowledge of the natural history of impacted third

molars and the current indications and strategies for third molar removal, and discuss the appropriateness of prophylactic third molar removal. To further elucidate these subjects, public health aspects on third molar surgery are included and so also are relevant aspects on judgement analysis and clinical decision analysis.

Definitions, prevalence, and public health aspects

An impacted third molar is a developmental anomaly caused by an obstruction in the eruption path or by an ectopic position of the tooth. The etiology of third molar impaction has been well reviewed by Svendsen and Maertens.⁹ From a surgical point of view, the degree of impaction and the position of the impacted third molar have been divided into different categories. Most classifications were developed for preoperative judgement of surgical difficulty and are based on radiographs.¹⁰ In this text the degree of impaction is classified as: (1) partially covered by soft tissue; (2) completely covered by soft tissue; and

(3) completely covered by bone tissue. The angular position of a third molar is classified as vertical, mesioangular, distoangular, or horizontal, according to the criteria described by Winter (Fig. 13.1).¹¹ These classifications can be used when comparing the results of different clinical studies, especially those concerned with the development of associated pathology. Winter's classification is a practical description for clinical use. For a more scientific evaluation of the third molar angulations described, the definitions of Shiller can be used.¹²

Management of an impacted third molar may include surgical exposure, transplantation, removal of the impacted molar or long-term observation in cases where a decision is made for retention of the impacted tooth. Indications for surgical exposure or transplantation are not included in this chapter. *Therapeutic third molar removals* are performed when a patient reports subjective symptoms from the wisdom tooth in combination with clinical signs of local pathology or when a patient is asymptomatic but clinical examination reveals third molar-associated pathology. In contrast to the therapeutic indications for third molar removal the *prophylactic removal of*

Fig. 13.1 The angular position of third molars according to Winter.¹¹

asymptomatic wisdom teeth is defined as the surgical removal of a third molar in the absence of subjective symptoms as reported from the patient as well as absence of local disease as registered by a dentist or an oral and maxillofacial surgeon.

Prevalence

Most studies on the prevalence of third molar impaction are based on patient materials from hospitals, dental schools, private practices, and army clinics.¹³ An ideal epidemiological study of disease or anomaly prevalence should be performed as a random sample of a well defined population, preferably representing the community as a whole. Such a study was performed by Hugoson and Kugelberg, and was based on 693 dentate persons aged 15–80 years from a random sample of individuals in a Swedish community.¹⁴ Approximately two thirds of individuals aged 15–80 years had between one and four third molars. Out of these wisdom teeth, 30.4% and 43.8% were partially or completely impacted in men and women respectively. In this study, the angulations of the impacted third molars were also presented and it was found that vertical angulation was most frequent (61.8%) followed by mesioangular (25.5%), distoangular (8.7%), and horizontal position (4.0%).

A suitable age for studying the frequency of third molars and their impaction should be about 20–25 years. In later age groups early extractions of third molars may escape notice and result in a too high frequency of individuals with no or lesser number of third molars. In a study of Swedish dental students¹⁵ aged 20–39 years (86% of them aged 20–29 years) it was found that 10% of the individuals lacked all third molars and half of them had all four third molars. One or more impacted third molars were found in 33% of the examined students. Calculated by number of teeth, 24% of all third molars were impacted, mostly in vertical or mesioangular position. Considering the prophylactic indication for third molar removal, these 24% of the third molars present in this age group represent primarily the third molars “at risk”.

It appears that the prevalence of third molar impaction increased during the second half of the 20th century. In a study from Finland¹⁶ it was reported that 29% of lower third molars were partially erupted in 1990 compared to 19% in 1949. Improved dental health in children and young adults, based on preventive dental programs, can be reflected in a marked decrease in first molar extractions. In modern man, with less attrition, this may result in a lack of space for normal third molar eruption. This epidemiological change in general oral health and third molar impaction has also been reflected in oral surgery practice where studies in the UK have shown a 40% decrease in routine extractions of permanent and deciduous teeth between 1974 and 1984, while surgical extractions increased by 113% during the same period.¹⁷

From the studies on the prevalence of third molar impaction one can conclude that:

- the most frequently impacted teeth are mandibular and maxillary third molars;
- at the population level, third molar impactions occur with a prevalence of 17–32%;
- in young adults, aged 20 years, 46% of the maxillary third molars were partially or completely impacted while the corresponding rate for mandibular third molars was 73%;
- females have third molar impaction more often than males;
- the prevalence of impacted third molar increased during the second half of the 20th century;
- the prevalence of impacted third molars indicates that health care resources allocated to third molar surgery are significant.

Public health aspects

Volume of surgery

Third molar removal is a high-volume surgical procedure. These operations can take place in general dental practice, both in the public health sector and in private practices, and by specialists in oral surgery in hospitals as well as in private specialist practice. In the UK, during the year 1989–90 almost 116000 patients in the National Health Service (NHS) and 22000 patients in the private sector had third molars removed.^{18,19} At this time removal of impacted teeth ranked number nine in the top ten list of procedures in the NHS and number one in the corresponding list of procedures covered by private medical insurers.²⁰ In 1989 oral surgeons in the public health sector in Sweden surgically removed 28000 third molars corresponding to 62% of all operations performed by those surgeons in that year.²¹ In Norway, with a population of 4.5 million, about 75000 impacted third molars were surgically removed in the early 1990s, about 75% removed by general dental practitioners (GPDs).²² In the US oral surgeons alone removed 2.25 million impacted teeth in 1977, the majority of which were third molars.²³ More recent statistics from the US report a marked increase in those procedures and in 1999 it was estimated that oral surgeons and GDPs removed 7 million and 3 million third molars respectively.²⁴ In a questionnaire reported in 2006, oral and maxillofacial surgeons in the US performed on average 53 third molar cases per month. With a variation of one to four third molars removed per patient and approximately 5500 practicing oral surgeons, it could well be that still at least 7 million third molars are annually removed by specialists.²⁵

On a population basis, an average of 281 third molar removals per 100000 people were performed in Sweden in 1989 by oral surgeons. The exact number of third molars removed by GDPs in Sweden is not known but has been estimated at around 1100 per

100 000 people. In Norway oral surgeons and GDPs together removed about 1600 third molars per 100 000 inhabitants. Toth¹⁸ estimated the third molar operation rate in the UK to vary from 250–680 per 100 000 people based on statistics from the South West Regional Health Authority in 1989.

A public health perspective also includes a valuation of how available health care resources are used. Regarding third molar surgery, it would be of interest to estimate the proportion of resources allocated to the removal of third molars associated with and without pathology. This is not easily assessed from the literature, mostly due to terminological inconsistencies when reporting indications for removals in surgical case series. Table 13.1 provides a summary of studies where the relative frequency of third molars removed, described as prophylactic removals, asymptomatic third molars or third molars without pathology are presented.

Costs

Large amounts are spent annually on third molar removals by public health authorities, health insurance companies, and patients. The total amount is very difficult to assess. From a public health aspect an estimation of cost for third molar surgery should include direct costs (health care facilities, professional salaries) as well as indirect costs (patients' loss of salary, travel expenses). When reported, the costs usually refer only to the direct costs. In 1989/90 the annual cost for third molar surgery in the NHS in England and Wales was estimated to be £23.3 million.¹⁸ In the US the costs for third molar removals in 1999 performed by both oral surgeons and GDPs were estimated to be \$3302 million.²⁴ Moreover, Friedman assessed that this volume of surgery involves about 5 million patients with an additional 11.3 million days of standard discomfort or disability postoperatively, an indirect cost that was not estimated in monetary terms.

Natural history of third molar impaction

Knowledge of the natural history of a disease, a condition or a symptom is a cornerstone in clinical decision making. In our case, the natural history of third molars includes descriptions of normal and disturbed eruption, prediction of third molar impaction, the prevalence of and risk for developing third molar-associated pathology, and reasons used for the removal of third molars. Most valid information of the natural history of a condition can be reached by following this condition in a well defined population for an adequate time – a longitudinal study. For an abnormal condition such as an impacted third molar, an expected follow-up time can be several years and even decades. In most circumstances this can be both extremely costly and impractical, and much of our knowledge is based on cross-sectional studies – different individuals studied at certain, different age-groups.

Eruption

If a third molar is considered erupted when any part of the crown has pierced the oral mucosa and become clinically visible, the mean age of eruption for lower third molars was 19 and 20 years of age for men and women respectively.³⁰ Completely erupted third molars in functional occlusion are very rare at the age of 20. When following the fate of non-erupted third molars in Danish dental students after the age of 20 in a 4-year clinical follow-up³¹ it was found that:

- none of the participating students had completely erupted third molars at age 20;
- 31% of the partially or totally impacted third molars at age 20 were completely erupted 4 years later;
- 38% of the third molars had been removed during the 4-year follow-up. The reason for removal was

Table 13.1 Data from surgically treated third molar patients. Relative frequency of third molars removed classified as asymptomatic, without pathology or as prophylactic extractions.

* To prevent future problems as stated by the patients.

mild clinical symptoms (e.g. feeling of pressure) in 39%, pericoronitis in 26%, caries in 4%, and a prophylactic indication in 31%.

In a similar study in Helsinki, Finland,³² the third molars of university students were followed clinically and radiographically for 6 years between the ages of 20 and 26 years. The main purpose was to study how many of the clinically invisible or partially impacted third molars at the age of 20 had erupted by the age of 26. It was reported that:

- at both baseline and 6 years later, upper third molars were more often erupted than lower ones;
- mandibular third molars completely impacted in soft tissue at the start of the study were more frequent in women (52%) than in men (31%);
- almost half of the third molars that were partially erupted at age 20 erupted during the 6 years' follow-up.

The findings of these two studies on university students were confirmed in a prospective cohort study in New Zealand³³ where the participants were followed from age 18 to 26. The conclusion of this study was that, with the exception of horizontally impacted third molars, a substantial proportion of other impaction types do fully erupt.

After the age of 25 there can still be some changes in eruption status of third molars, but these changes are insignificant compared to the more dynamic period for third molar development between 18 and 25 years.^{34,35} It can thus be summarized that third molars do continue to erupt after the age of 20 until 25–26 years of age. In the age group 20–26 years, in the absence of subjective symptoms or local disease, the strategy of choice for third molars seems to be observation rather than prophylactic removal.

Pathology related to third molars

The justification for routine removal of all third molars that do not reach functional occlusion is the belief that those teeth constitute an abnormality with a significant pathologic potential. Some 20–30 years ago, such a belief was supported by published case series of patients with serious pathologic consequences of third molar retention. While each case presents a convincing indication for surgery for that individual patient, the presentations were not balanced with the known or estimated prevalence of that particular condition.

There are three main kinds of studies that have shed some light on the prevalence of or risk for pathology related to non-erupted third molars. One type of study is the prospective follow-up of defined populations while other studies report data from surgically treated patient groups or otherwise defined patient populations. The most convincing evidence comes from prospective, long-term follow-up studies

of a defined population of individuals with non-erupted third molars at the baseline of the study. Preferably, persons to be included in such a study are around 20 years of age at baseline. To be sure that you will obtain relevant information, even for pathologic entities with low prevalence, the selected population has to be followed for 15–20 years and the number of individuals to be followed can be estimated to be at least 500–1000. Even if this suggested design is followed, one would certainly fail to detect those extremely low-frequency conditions which appear in middle-aged or older people. Knowledge of those entities is probably best found in data from series of surgically treated third molar patients. For many practical, logistic and financial reasons, an ideal prospective study designed as mentioned above has not yet been published.

Follow-up of defined populations

Except for the studies of third molar eruption in young adults mentioned above, the most ambitious follow-up study on clinical changes in third molar status in a defined population is that reported by Ventä and co-workers.^{36,37} They followed a population of 181 university students in Helsinki with clinical examination at the age 20, 26, 32, and 38 years. The clinical examinations were supplemented with panoramic radiographs at 20, 32, and 38 years of age. While the studies were mainly concerned with changes in third molar eruption status, it was also found that after 12 years, at age 32, 47% of the third molars were removed. At the age of 38, after 18 years' follow-up, 73% of the initially non-erupted third molars (soft tissue and bone impactions) were removed. For the initially partially erupted third molars, 64% were removed during the follow-up period. In the 12-year follow-up, it was however reported that 61% of the individuals with removals presented no symptoms while 35% of those with removals sought treatment because of symptoms. It was also shown that there was a peak in extraction frequency at 27–28 years of age. The aim of these studies did not include registrations of indications for those third molars removed, but it is quite plausible that a considerable number of those third molars without symptoms were, according to the current concept of indications at that time, removed prophylactically.

A longitudinal, 12-year follow-up was performed on a cohort of Swedish women aged 38–60 years at inclusion.³⁸ The participants were examined with panoramic radiographs at baseline as well as 12 years later. A total of 166 impacted teeth were found in 8% of the 1418 participating women. The majority of those impactions were third molars (85%). The findings of third molar-associated pathology in this study are summarized in Table 13.2. Most conditions were regarded as moderate (slightly widened follicle or resorption of the crown) and only in 1.2% of the

Table 13.2 Prevalence of third molar associated pathology in middle-aged and older women. From a 12-year follow-up study by Ahlqvist and Gröndahl.³⁸ In the baseline study, 8% of 1418 women had impacted teeth, 85% of them third molars. At the 12-year follow-up, 114 of the initially 166 examined impacted teeth could be re-examined. 18 impacted teeth had been removed during this period and 34 were found among those women not participating in the follow-up study.

	Baseline of study	12-year follow-up
Number of impacted teeth	166	114
Associated pathology		
Follicular cyst	1.2%	1.7%
Widened follicles (3–4 mm)	8.4%	7.9%
Crown resorption (third molar)	6.6%	8.7%

impacted teeth could a genuine follicular cyst be observed. At the 12-year follow-up unchanged conditions were found in 85% of the cases; 18 impactions had been removed, only two of them with associated pathology.

In a recent study from Cardiff, Wales, Hill and Walker³⁹ followed 228 persons with a total number of 427 third molars for a 5-year period. The median age at inclusion was 23 and the female:male ratio was almost 2:1. Of the 228 recruited persons, 150 remained symptomless during the 5-year follow-up. A total of 66 persons had a previous history of pericoronitis at inclusion and 23 of them had a third molar removed during the study. In addition to these 23 persons, another 48 had third molars removed during the study. The main indication for surgery in those cases was pericoronitis (30 out of 48 patients) while the other indications included caries in second molar, orthodontic treatment, food impaction, and pain.

Data from surgically treated third molar patients

Some valuable information can be gathered from studies on patients referred for third molar surgery. When one makes inferences from those data it is, however, important to recognize that they are biased for several reasons. For one thing, referral patterns differ between different countries due to varying degrees of specialization, financial organization of the health care system, and the socio-economic status of the population. The selection of patients may also vary considerably if the patients in the study represent referrals to private practitioners in oral surgery, a county hospital department, or a highly specialized university clinic. It is also evident that definitions of pathologic entities can vary, a fact which is quite obvious when you study the prevalence of follicular cysts.⁷

From the studies presented in Table 13.3 we can observe that there is a considerable variation in the prevalence of reported pathosis in surgically removed mandibular third molars.^{28,40–46} Pericoronitis as cause for removal varies from 6–53% of the cases and, in the

majority of the studies, was the most prevalent pathologic entity. Other diseases related to the third molars were less frequent, except for a deviating, high prevalence of caries on the second molar (42.7%) in the study of van der Linden and co-workers. Their findings were based on a retrospective study of panoramic radiographs and hence pericoronitis prevalence was not included. Resorption of the distal root surface of the second molar was noticed from less than 1% up to 6% of the cases. Although these studies represent third molars scheduled for removal, more serious diseases such as follicular cysts and tumors were less frequently reported. Cysts were generally found in the range of 3–6% of the operated cases. When tumors were diagnosed in relation to a third molar, the prevalence of such a pathosis was less than 1%. In the extensive surgical material from the university clinic of Oral and Maxillofacial Surgery in Ankara, Turkey, tumor was the indication for third molar surgery in 0.79% of the cases; 98% of them were odontogenic tumors and 2% were malignancies.

Other studies on dental patients

Some information on the natural history of third molar retention can be gained from cross-sectional studies on dental patients. Such patient populations differ of course from the surgical patient groups in that they are primarily not investigated clinically or radiographically because of a third molar problem or referral. It is also important to observe that patients, who have had third molars associated with clinical symptoms and obvious pathology, have already had these molars removed. Thus, symptoms and pathosis registered at various age-groups in these cross-sectional studies probably represent a minimum of possible pathologic sequelae to third molar retention.

Table 13.4 presents cross-sectional patient studies where the aim was to assess the possible complications. Stanley and co-workers⁴⁷ published a radiographic study on a large cohort of dental patients from a Veterans Administration Hospital and a university college of dentistry in Florida, USA. They reviewed the panoramic radiographs and dental and medical records of 11598 persons seeking dental treatment. The mean age of the patients was 47 years, and it was found that 1756 patients had 3702 impacted teeth (95.6% of them were third molars). Of the impacted teeth, about 8.8% showed some signs of pathology. Follicular cysts were present in only 0.31% of the impacted teeth. Presenting the radiographic changes on a per patient basis, a total of 12% had an impacted tooth with an associated radiographic lesion.

Another patient cohort was presented from the Karolinska Institute, Stockholm, Sweden by Eliasson and Heimdahl.⁴⁸ They examined radiographs of 644 randomly selected patients (mean age 42.6 years) with 1211 impacted third molars. Conditions like follicular cysts, resorption of second molar, and severe

Table 13.4 Cross-sectional studies on dental patients. Prevalence of pathologic lesions associated with impacted maxillary and mandibular third molars.

Reference	Age of patients	Number of third molars	Resorption, second molar	Cysts	Periodontal problems	Study characteristics
Stanley <i>et al.</i> 1988 ⁴⁷	20–83	3702	3 (incl.caries)	0.8	4.5	Radiography, mandible and maxilla
Eliasson <i>et al.</i> 1989 ⁴⁸	>30, mean age 42,6	1211	0.9	4	4 (maxilla) 1 (mandible)	Radiography, retrospective

loss of marginal bone on the distal aspect of the second molars were found in 6.9% of the impacted third molars. Furthermore, 5% of these impactions showed crown resorptions.

From the three different kinds of cohort studies (follow-up of defined populations, third molar surgery patients, and cross-sectional studies on dental patients), the least reliable source of information on the prevalence of third molar-associated pathology in the general population can be derived from the surgical patient groups. The most promising result can be expected from prospective long-term follow-up studies of defined populations. Existing studies, however, lack in strength by having either too few third molars included or too short a follow-up time. From cross-sectional studies on dental patients we can observe that third molar impactions still present in middle-aged or older patients are associated with a rather limited prevalence of pathology (approx. 7–9%). There are also indications that impacted third molars without any signs of pathology in these age groups will be unchanged, with only a limited risk of becoming associated with serious pathology over a relatively long period of time. One conclusion for clinical decision making may be that relatively long intervals can pass between radiographic re-examinations of disease-free, asymptomatic impacted teeth found in those age groups. It is also important to observe that the majority of the studies were based on radiographs. Clinical findings such as chronic pericoronitis, food impaction, incipient caries, and periodontitis were not recorded.

Impaction status and angulation of the third molar

It is not an unexpected finding that the risk for developing associated disease varies with the type of impaction of the third molar. Obviously, third molars partially covered by soft tissue have a much higher exposure to local disease-inducing factors than those third molars totally covered by soft tissue or those completely embedded in bone. In a study of the mandibular third molar position as predictive criteria for risk for pericoronitis in young adults⁴⁹ it was found that 97.5% of the pericoronitis cases were partial soft tissue impactions and only 2.5% were fully impacted in soft tissue. This higher risk for pathology associated with partial soft tissue impaction was also confirmed in studies on other patient cohorts. In the studies of Ventä *et al.*⁵⁰ and Knutsson and co-workers,²⁸ third molars partially covered by soft tissue presented a much higher risk for pathology than third molars totally covered by soft tissue or bone (odds ratio 6.4 and 6.7, respectively). On the other hand, pathologic entities such as follicular cysts are only associated with impacted teeth totally covered by soft tissue or bone.

When estimating the risk for pathology, it is reasonable to combine the eruption state and the angular

position of the third molar. Leone *et al.*⁵¹ described the tooth at highest risk for acute pericoronitis as a vertical or slightly distoangular positioned mandibular third molar that is in contact with the second molar, at or above the occlusal plane, and partially covered by soft and bone tissue. In contrast, Ventä *et al.*⁵⁰ found that the most common mandibular third molars that gave rise to acute problems (mostly pericoronitis) were distoangular-oriented and partially embedded in soft tissue. The odds ratio for development of pathology was, according to Knutsson *et al.*²⁸ about 5–12 times higher for distoangular third molars compared to other angular positions. They found that mesioangular molars presented the lowest odds ratio, 0.5, compared to 5.8 for the distoangular-oriented third molar.

General aspects on clinical decision making

The quality of health care in every clinical specialty depends mainly on two factors: the quality of the judgements and decisions on what to do, and the quality of how these interventions are performed practically. Interventions in this context may be a decision to perform a diagnostic test, a surgical procedure, administration of a medication, or a decision to “wait and see” the natural outcome of a symptom or clinical finding. Thus, it is easy to appreciate that everyday clinical work involves a lot of judgements and decisions. For surgeons, it is important to recognize that in spite of an excellently performed surgical operation, if it is based on a poor decision, the outcome for the patient may be suboptimal or even harmful. One also has to acknowledge that clinical decisions create costs: (1) monetary costs for health care providers, society, insurance companies and patients; (2) for patients, in addition to the financial burden of the intervention, there are also the costs of the morbidity of that particular disease and intervention. Therefore, in an era of limited health care resources, research that promotes the quality of clinical judgements and decisions is of importance for clinicians as well as for health care administrators, who all are under pressure to provide medical and dental care cost-effectively. Research on and implementation of clinical decision making is an expanding field which demands contributions from different fields of science such as medical and dental specialists, psychologists, economists, decisions theorists, and statisticians. For those readers who want to develop their interest in this area of health care, a review edited by Chapman and Sonnenberg⁵² is recommended.

Judgement analysis

A clinician's decision on a specific diagnosis or recommendation of a specific intervention is preceded by judgements on a number of cues characterized

by uncertainty. Such judgements can be interpretation of laboratory data, radiographs, findings on a physical examination, and soft data from interview of the patient. Excellence in clinical work is to combine the judgements of different cues to a decision with a high accuracy to a "true state", e.g. the outcome of the intervention or the confirmation of the diagnosis with a recognized "gold standard". It has, however, been shown that there is a substantial variation in judgements in almost every aspect of clinical practice. In a review article, Eddy states that *"in general, observers looking at the same thing will disagree with each other or even with themselves from 10% to 50% of the time"*.⁵³

Social judgement theory (SJT) as described by Brehmer⁵⁴ in 1988 has inspired a lot of studies on how clinicians and other professional decision makers combine and integrate probabilistic information. Judgement analysis is a descriptive approach to analyze medical decisions and Brunswik's lens model (Fig. 13.2) is a conceptual model commonly used in such studies as described by Wigton in 1988.⁵⁵ Brunswik used the analogy of rays of light passing through a convex lens to describe the relationship between the interpretation of information (cues) and the actual relationship of those cues to the true state. Judgement analysis has been applied in several areas, such as medicine, psychology, education, social work, and business. In the medical domain, several aspects of clinicians' judgement have been studied, both in the process of making a diagnosis or prescribing an intervention. Reviewing some of these studies Wigton⁵⁶ concludes that a most important finding was the surprising degree of variation in the judgement of experts in medicine. He also concludes from the policy-capturing studies that cues given considerable weight by some clinicians may not be recognized

as important by other physicians or by textbooks. A series of important papers on professional judgement, many of them on clinical decision making, has been assembled by Dowie and Elstein.⁵⁷

Judgement analysis and third molar surgery

With the Brunswik lens model as a conceptual model, Brehmer, Knutsson, Lysell, and Rohlin^{58–65} published a series of papers on dentists' judgement in the removal of asymptomatic mandibular third molars without associated pathology. The studies were based on 36 mandibular third molars referred for removal and were selected with the aim of representing an equal distribution of males and females, of different age groups of patients, as well as of different angular positions and degree of impaction of the third molars. Each case was presented to the clinicians participating in the study as a radiograph and a questionnaire. Next to the radiograph a short text informed the participant about the sex and age of the patient and the degree of impaction of the third molar. The clinicians were asked to decide whether or not to remove the third molar in question, and furthermore to establish the degree of confidence with which they judged the need for removal (named the indication index) on a 100mm visual analog scale (VAS). For each third molar presented the participants had to estimate the probability for development of pathology in general and for six specified pathologic entities, also on a 100mm VAS.

Initially, 40 clinicians from Sweden were included in the study, 30 general dental practitioners (GDPs) and 10 oral and maxillofacial surgeons (OMFS). In a later part of the study another 18 GDPs and 10 OMFS from Wales were included for a comparative study between dentists' judgement on preventive third

Fig. 13.2 Brunswik's standard lens model, copied and adapted from the papers by Brehmer,⁵⁴ Wigton *et al.*,⁵⁵ and Knutsson.⁶⁵ The cues can be clinical symptoms or signs in a diagnostic or therapeutic judgement. A linear model of the judges (clinicians) is calculated from repeated judgements on the right side of the lens, while a model of the true state (or the outcome) is calculated from repeated observations of real outcomes on the left side. Accuracy (r_a) is represented by the correlation between the judgements and the actual outcomes.

molar surgery in Sweden and Wales. The paragraphs below summarize what we have learned from those studies:

1. There were substantial variations, both among individual GDPs and OMFS, in the decision whether or not to remove asymptomatic mandibular third molars. The number of molars the 30 GDPs proposed for removal varied between 0 and 26 of the 36 presented cases. For the OMFS the corresponding figure varied between 3 and 21 third molars. There was no third molar among the 36 cases that all observers in the two groups agreed should be extracted. However, the OMFS were unanimous in the judgement *not* to remove 11 of the 36 third molars.
2. There was no significant correlation between the level of professional experience and the judgement whether or not to remove asymptomatic third molars either among GDPs or OMFS as a group.
3. The VAS is an appropriate tool for rating an indication index in judging the need for removal of asymptomatic third molars. There was no overlap of the 95% confidence limits for third molars proposed for removal versus third molars not proposed for removal.
4. As part of the lens model concept, multiple linear regression analysis was performed to determine the relative weights of the specific pathologic entities given by the participants in their judgement of the perceived likelihood of development of pathology in the asymptomatic third molars. The GDPs estimated the highest weights to cyst formation and pericoronitis, whereas the OMFS gave pericoronitis the highest weight and considered caries in the second molar as important as development of a follicular cyst. The risk for neoplastic changes and root resorptions on the second molar received low weightings. For certain entities, such as cyst formation, the weights given by individual participants varied widely from almost zero to very high weightings.
5. The influence of the three cues, age of the patient, angular position of the third molar, and impaction status of the third molar, on the judgement to remove an asymptomatic third molar, showed a considerable variance regarding individual judgements. Third molars partially covered by soft tissue were given the highest indication index for removal by both groups of clinicians. As a group, GDPs estimated the need for removal to be higher for patients below 40 years than those above this age. OMFS, however, estimated the need for removal to differ for the three different age groups (19–25 years, 26–40 years, and 41–60 years), giving the highest indication index to the youngest age group and the lowest for the oldest age group. Overall, the mean proportion of variance explained by the three cues was high, indicating that the clinicians used the three cues and the combination

of them to a great extent in their judgement of the risk for development of pathology that can be associated with an asymptomatic third molar.

6. Studying how the participants integrated the cues as compared with existing evidence in the literature showed a wide variation in judgement strategies. Only one person, a GDP, integrated the three cues according to the evidence.
7. In a comparison between clinicians in Sweden and Wales no evidence was found in mean numbers of third molars scheduled for removals by the GDPs. The Swedish oral surgeons, however, scheduled significantly more third molars for removal than the oral surgeons in Wales. This difference was interpreted as a result of the development of authoritative guidelines in the UK.

Judgement analysis does not bring new information on *why* and *when* a third molar should be removed. This method can be used to characterize how dentists weigh clinical information in reaching a judgement of intervention as well as non-intervention. The result of those studies can also be of advantage in undergraduate as well as postgraduate education to give students awareness of the difficulties in probabilistic judgements. The results can also reduce an often prevalent overconfidence in holistic judgements and encourage students to compare their own judgement strategies with those of their fellow students and with published results and existing evidence.

Decision analysis

Decision analysis is an approach that combines clinical data mathematically for developing an explicit decision making under uncertainty. As written by Dowie and Elstein:⁶⁶

Decision analysis decomposes any decision problem into discrete components and provides a procedure for synthesizing these components into an overall measure of the attractiveness of each possible action – its expected utility – so that the *optimal* strategy can be selected.

Decision analysis has been used for diagnostic as well as for treatment and prognostic decisions in medicine for decades^{67–70} and its use in dentistry has been thoroughly reviewed by Rohlin and Mileman.⁷¹ Decision analysis is described in detail elsewhere⁷⁰ but for those readers not familiar with the method a brief review will be given.

A decision analysis starts with a description of the decision problem faced by the decision maker. Currently, it is unrealistic to make separate decision analyses for individual patients and for that reason the decision problem has to be relevant for groups of patients with similar clinical features. The major components of decision analysis are the structure of the model of the decision problem (commonly using

a decision tree, Fig. 13.3, as a visual representation of the decisions available), assigning probabilities to the outcome events incorporated in the model and assigning utility values to each outcome. A utility value represents the strength of a patient's preference for one outcome over others. Utility values can reflect several dimensions of an outcome, for example life expectancy, quality of life, morbidity of the intervention, and costs. In this way it has been suggested that decision analysis reconciles evidence-based medicine with patients' preferences. In many clinical decision problems the assignment of utility values is *per se* a complex research process where people or patients have to assess the different dimensions of an outcome in order to arrive at a single index value for a future health state. Often the best health outcome is given the index value "1" and the worst possible outcome is given "0". In some more basic decision analyses patients' preferences are substituted with the decision makers' own estimation of morbidity and costs. Finally, when the expected value of each decision option has been calculated, a sensitivity analysis is used to determine the robustness of a choice made using this method. This is done by repeating the analysis and at the same time varying the outcome probabilities and utility values within clinically realistic limits to see how easily a decision would change – in other words to see how sensitive it is.

Even if decision analysis has not yet been incorporated in the face-to-face consultation between doctors and patients it is an increasingly used research tool, at least in medicine, and it also helps the clinicians to inform, in a more explicit way, patients of possible choices and their associated benefits and harms.

Decision analysis and third molar surgery

Two research-groups, Tulloch *et al.*^{7,23} and Brickley *et al.*^{6,73} have used the decision analysis approach to calculate the optimal strategy for the management of the mandibular third molar. The design of their studies varied in how probabilities of outcomes were estimated and also in their assessment of utilities. The conclusions of their studies did not, as we shall see, differ.

Tulloch *et al.* considered what treatment recommendations should be made by clinicians to healthy young adolescents with an incompletely developed or erupted mandibular third molar. In the study they compared three alternatives: (1) extract each third molar prior to complete root formation; (2) delay the decision to extract until the third molar has no further potential for eruption, then extract only those third molars that remain totally or partially impacted; (3) extract only those third molars that become associated with some type of pathology. The outcomes they considered are the disability and costs associated with the pathology, surgery and complications of each strategy. The probability of different pathologic entities was obtained from the literature, while the probability of complications with surgical extractions related to the type of impaction, and presence or absence of pathology were estimated by nine oral surgeons in a so-called Delphi process. Each complication was assigned an equivalent number of "days of standard discomfort" (DSD) and the valuation of the DSD was performed by 46 randomly selected dentists. A detailed calculation of costs was performed, including surgeons' fees, radiographic examinations, operating room facilities, anesthesia, postoperative medication, and follow-up visits.

Fig. 13.3 Structure of a decision tree. A basic decision model starts on the left-hand side with a *decision node* (square). This node indicates the fundamental decision to be made, in this example prophylactic third molar removal versus watchful waiting. *Chance nodes* (circles) describe various events that are subject to chance and are not under the control of the decision maker. Each possible outcome is associated with a certain probability that it will occur (p_1 through p_4). All of the probabilities at a specific chance node must sum up to 1. Each branch in the decision tree ends with a *terminal node* (boxes) representing the *utilities* (U_1 through U_4) of ending up in a particular outcome state. In a decision problem with only two choices, each with two possible outcomes, the *expected value* of Choice 1 is simply the sum of the possible outcomes of that choice weighted by the probabilities of each outcome: $p_1U_1 + p_2U_2$. Consequently, the *expected value* of Choice 2 is: $p_3U_3 + p_4U_4$. The branch with the highest value at the decision node is the recommended choice.

Finally, the expected outcome for each of the three treatment strategies was expressed as the sum of all possible costs and disabilities under that specific strategy. The result was an expected cost (in 1985 US dollars) and DSD for each strategy and should be interpreted as the cost per person if that strategy was universally applied. They found in this calculation, including a sensitivity analysis, that strategy 3, only extractions of third molars associated with pathology, was the optimal strategy with the lowest expected costs and disability.

Brickley *et al.*⁷³ performed a decision analysis with the alternatives: extract or leave the third molar *in situ*. The probabilities of the outcomes were estimated from a comprehensive literature review and a clinical audit. The utility values were based on data from 104 individuals who rated on a VAS their perceptions of different health states resulting from extraction of as well as leaving a mandibular third molar *in situ*. The vignettes that were used to describe the health states included descriptions of possible complications of surgery and different pathologic entities that could develop in association with third molars left *in situ*. They did not, as Tulloch and co-workers, include the monetary costs for the two strategies.

When performing the decision analysis they found that the maximum expected utility of prophylactic third molar surgery was lower than that for non-intervention. Sensitivity analyses showed that the probability for recurrent pericoronitis has to be greater than 0.52 (52%) before the optimal decision would alter from non-intervention to surgical removal. The corresponding threshold value, e.g. the probability value at which the optimal decisions changed from non-intervention to surgery, was found to be 0.34 (34%) for a cystic change.

The important contribution of the study by Brickley and his team is their inclusion of patients' value when assessing the expected utilities. Both research groups integrated what was then the current knowledge of impaction prevalence, disease prevalence, probability of complications after surgery, and risk for future pathology in case of non-intervention as reported in the literature or by some kind of clinical audit. Some of those estimations were impaired by great variations. Because decision analysis is laid out in a formal and explicit way, the method has at least the advantage of identifying areas where evidence is absent or scarce.

Patient preferences

Decision making in medicine and dentistry involves evaluating outcomes in relation to both patients' and clinicians' preferences and values. An evaluation must be made whether the benefits of a certain intervention outweigh the physical, social, and emotional discomfort as well as the risk of serious complications. The last 20–30 years have witnessed a radical change of power in clinical decision making from a

more paternalistic approach from health care professionals to a situation of shared responsibility between patients and professionals for treatment decisions. At one extreme, patients have been described as informed consumers making decisions on what treatment to purchase, reducing health professionals to technical providers of certain services. A more common and realistic scenario is that patients want to be well informed and have an active role in the discussion of possible treatment choices. This demands an improvement in the quality of information given to patients but also a deeper understanding by clinicians of patients' preferences for the various outcomes of different interventions. Individual decision making, and also development of guidelines for specific disease entities and formulation of health care policies on a societal level, have created a need for a more explicit assessment of patient preferences.

Utility assessment is the technique most often used to evaluate patient preferences in clinical decision making. In medical decision making the most frequently used methods of assessing utilities are the Standard Gamble, the Time Trade-off, and VAS. The pros and cons are well reviewed by Stiggelbout.⁷⁴ Utility values are often generated by groups of patients with a similar clinical condition, and are preferably used for decisions at the group level, i.e. for development of clinical guidelines. When making decisions for the individual patient, the purpose is not to use absolute utility scores, but they can, however, be useful to help a patient to clarify his or her values. Utility assessment is a complex cognitive process as it involves rating different health states when faced with uncertainty. It is also important to remember that a certain health state involves physical as well as social and emotional components. In the case of third molar surgery, it means that clinicians should not only consider the probabilities of well known complications, such as postoperative alveolitis, nerve injuries, and bleeding complications, but also incorporate the influence on patients of the effects of a normal postoperative course such as pain, swelling, and trismus. Furthermore, Stiggelbout states that "*the elicitation of utilities for transitory, non-chronic health states is more complicated than for chronic, stable states*".

One methodology, the multi-attribute utility (MAU), as described by Torrance *et al.*⁷⁵ allows incorporation of both medical and non-medical factors in utility assessment and has been applied in studies of patient preferences on the removal and retention of mandibular third molars.^{76–78} The process is time-consuming and comprises three stages:

1. Elicitation of domains. These are main areas, such as general well-being, social life, work or studies, and economic situation, which patients generally consider to be important in their lives in relation to the intervention or disease under investigation.
2. Intra- and interdomain weighting.

3. Rating of outcomes. Different outcomes are often presented in short vignettes describing various health states related to a particular disease or intervention.

A preference value (or utility) for each vignette/health state and each patient is calculated using a special formula incorporating the result of each of the three stages. For the interested reader, the MAU-process is presented in detail in relation to third molar removal or retention by Liedholm and co-workers.⁷⁷

Using the MAU methodology, patient preferences were assessed by similar groups of patients in Sweden and Wales referred for removal of one or both mandibular third molars. The participants were recruited after a consultation with an oral surgeon but before

any intervention was performed. None of these patients had any earlier experience of third molar surgery. The preference or utility values and the relative ranking of the 18 different health states are presented in Table 13.5. There was an overall agreement between patient preferences and their ranking in the two countries. Generally, the results indicate that patients estimate that third molar removal had a more negative impact on their lives than a strategy of non-removal. Of interest for the practicing surgeon is the negative impact of postoperative pain on the preference valuation. When third molar surgery has to be performed, a sufficient analgesic regimen must be prescribed to obtain optimal patient satisfaction. The results also indicate, e.g. in the case where the vignette suggested a follicular cyst and patients in Sweden

Table 13.5 Patients' preferences in Sweden and Wales when 55 patients in Sweden and 100 patients in Wales were asked to imagine the outcomes of 18 vignettes. Ranking (R) 1 represents the least annoying and ranking 18 the most annoying outcome. There was a high degree of correlation between the two countries ($r_s = 0.93$, $P < 0.001$). Vignette	Wales		Sweden	
	Mean	R	Mean	R
1 After the extraction you experience moderate pain and your face and mouth are very swollen	51.7	11	55.5	10
2 After the extraction you experience severe pain which keeps you awake for a few nights	37.3	17	38.8	16
3 After the extraction your jaw is stiff and painful. You have difficulty opening your mouth as wide as normal	55.9	9	43.5	15
4 After the extraction you experience minor discomfort and abnormal bleeding from the socket for a few hours	60.8	7	56.2	9
5 After the extraction you experience minor discomfort and also tingling and prickling sensations in your lower lip or tongue for up to 2 weeks	56.3	8	59.9	7
6 After the extraction you have minor discomfort. Your tongue is completely numb on one side for up to 6 weeks	50.5	12	52.5	11
7 After the extraction you have minor discomfort. Your tongue is completely numb on one side permanently	44.1	14	46.1	13
8 After the extraction you have minor discomfort. Your lower lip (but not your tongue) is completely numb on one side for up to 6 weeks	55.0	10	56.9	8
9 After the extraction you have minor discomfort. Your lower lip (but not your tongue) is completely numb on one side permanently	48.2	13	49.2	12
10 After the extraction you have minor discomfort. Your lower lip and your tongue are completely numb on one side for up to 6 weeks	42.8	15	45.9	14
11 After the extraction you have minor discomfort. Your lower lip and your tongue are completely numb on one side permanently	40.5	16	38.3	17
12 After the extraction the surgeon tells you that your jaw is broken and that you need your teeth wired together for up to 4 weeks	35.9	18	15.5	18
13 A tooth comes up at the back of your mouth. On one occasion this gives you a few days of aching pain and around the tooth the gum is swollen	85.0	2	78.8	2
14 A tooth comes up at the back of your mouth. Every six weeks or so you experience a few days of aching pain and around the tooth the gum feels swollen	73.8	5	70.4	3
15 The position of the wisdom tooth causes "gum disease" in the tooth in front which will make losing it more likely	71.8	6	64.9	6
16 You have a new tooth, which comes up, behind your last lower tooth. This results in the tooth in front becoming decayed and needing extraction	82.7	4	68.5	5
17 You notice that the appearance of your lower front teeth has changed slightly. The teeth appear to be more "squashed" together	83.7	3	80.5	1
18 After having an X-ray to find out if your wisdom tooth is present, the dentist tells you that there is a fluid-filled sac around your wisdom tooth and that this tooth must be removed	85.1	1	69.6	4

gave this health state the highest ranking (that is least negative effect on patients' life), that patients and professionals may interpret the seriousness of a certain health state quite differently.

In a shared decision on third molar removal an important aspect to discuss is the preferences of patients who had experienced third molar surgery. Such information is of value for the patient deciding on third molar removal, especially in cases of asymptomatic third molars or when prophylactic third molar removals are considered, and of course also to clinicians providing informed consent. Postoperative morbidity presented as biomedical measurements of swelling, trismus, and pain relief from different analgesic regimens has been extensively covered in the literature, while the issue of quality of life after third molar surgery has only started to attract researchers during the last decade. In 1996, when Shugars *et al.*⁷⁹ presented an instrument to measure patients' perceptions after third molar surgery they found that patients "*consistently talked about how their social activities were limited during the first 3 days after surgery*". The authors concluded that some kind of scale for ranking social activity and work have to be included when assessing the quality of life after this kind of surgery. They developed and modified this health-related quality of life (HRQOL) designed for the short-term outcome of third molar surgery and conducted a study with 249 patients.⁸⁰ The patients had to record their perceptions on four main areas each postoperative day for 14 days. These main areas, or domains, were pain, oral function (mouth opening, chewing, and talking), general activity (routine daily activities, recreation, sleeping, and social interaction), and other symptoms (bleeding, bruising, swelling, nausea, food impaction in surgical sites, and halitosis).

Using the same HRQOL instrument White *et al.*⁸¹ reported clinical as well as HRQOL data on the recovery of 603 patients who all had four third molars removed. This was a prospective study where patients were enrolled both in academic clinical centers and in community specialist practices. The follow-up for recovery was 14 days. Another research team in Dundee, UK⁸²⁻⁸⁴ developed a similar third molar outcome scale, PoSSe (postoperative symptom severity scale), which was validated by comparing it with a well validated measure of health, the anglicized version of the SF-39 health survey questionnaire. They found that the PoSSe-instrument was a reliable, valid measure of postoperative symptoms after third molar removal and of the impact of those symptoms on the perceived health of the patients. A brief summary of those studies reveals that:

- Social life was substantially affected during the first 3 postoperative days. A return to a more normal function was registered at postoperative day 5.
- Recreation and daily activities (work/studies) followed closely the development of social activities and was near normal 1 week after surgery (Fig. 13.4).
- Almost half of the patients experienced some pain 1 week postoperatively. One can expect almost all patients to take analgesic medication the first postoperative day and 1 week after surgery almost half of the patients were still in need of pain medication (Fig. 13.5).
- Bleeding and nausea were only a concern to patients during the first day after surgery.
- Chewing, mouth opening and swelling required 6, 5, and 4 days to attain minimal or normal levels.

Fig. 13.4 (a, b) Percentage distribution of patients ($n = 547$) indicating that third molar surgery interfered "quite a bit/lots" with lifestyle. From White *et al.*⁸¹ Copyright © 2003 Elsevier.

Fig. 13.5 (a, b) Percentage of patients taking analgesic medication after third molar surgery. From White *et al.*⁸¹ Copyright © 2003 Elsevier.

- Postoperative swelling was at its maximum during postoperative day 1 and 2 and had almost disappeared on postoperative day 5 to 6.
- Food collection and halitosis were still a problem for 15–20% of the patients on postoperative day 7.
- When comparing the perceptions of the impact of third molar surgery on the quality of life between patients, GDPs, and oral and maxillofacial surgery consultants, they were found to differ in some aspects. GDPs appeared to overestimate the impact of pain while patients ranked interference with daily activities and problems with chewing and enjoyment of food as more disturbing in the first postoperative period. Oral surgeons were in closer agreement with their patient; however, like the GDPs they also overestimated the impact of pain.

Of equal, if not of more importance, is the question of whether third molar surgery can improve the quality of life as perceived by patients in the long term. This is of course a more serious question when asymptomatic third molars or prophylactic removals are discussed. Is it realistic to assume that patients appreciate that the disability of the postoperative 7–14 days, together with estimated risk of complications, can be compensated by the assurance that third molar-associated pathology is eliminated? It is not an easy question from a researcher's perspective, as it includes the use of valid and reliable quality-of-health measures, both general and oral health-related, as well as cultural perceptions of health, risks and preoperative characteristics such as age, medical status, and severity of third molar pathology. There are indications, as presented in a study by McGrath *et al.*,⁸⁵ that patients perceive an "oral health gain", an improvement in oral health 6 months after third molar removals. This was more pronounced in patients having preopera-

tive symptoms (previous pericoronitis) compared to patients with asymptomatic third molars.

There are certain problems and limitations to extracting and analyzing relevant information of patients' perception of the postoperative quality-of-life after third molar surgery. Not only do outcome scores differ, so do surgical protocols. One study included patients where all four third molars were removed⁸¹ while patients in another study⁸³ had from one up to four third molars removed at the same surgical session. While one study reported only on patients operated on under general anesthesia⁸² another included procedures performed under local as well as intravenous anesthesia.⁸⁰

Indications for third molar removal

Therapeutic indications

There is a general agreement on well defined criteria for third molar removal that were the result of the consensus conference held by the National Institutes of Health (NIH) in 1979.⁸⁶ It was recommended that fully or partially impacted third molars should be removed when there is evidence of pathological changes. The criteria included infection, non-restorable carious lesion, cyst, tumor, and destruction of adjacent tooth and bone. Beyond those criteria it was also agreed that impaction or malposition of a third molar is an abnormal state and may justify its removal and that such treatment is not considered "prophylactic". Although there was no consensus on removal of asymptomatic impacted third molars without any evidence of pathology, the conference stressed the need for long-range studies on this subject. Furthermore it was agreed that enucleation of third

molar buds in young age groups was not acceptable and that there was little rationale for the removal of third molars solely to minimize present or future crowding of lower anterior teeth.

Following the NIH consensus conference, and inspired by its conclusions and suggestions for further research, quite a number of research papers and review articles have been published. Reports on clinical decision making, public health aspects on third molar surgery, and research aiming to assess the prevalence of third molar associated pathology and the natural history of third molar retention, referred to earlier in this chapter, are good examples. The reviews of Stephens *et al.*,⁴ Mercier and Precious,⁸⁷ Daley,⁸⁸ and Adeyemo⁸⁹ are also helpful. Since there is a general agreement on the indications for surgery when a third molar is associated with pathology, the controversy that still remains is over the treatment of asymptomatic third molars and the practice of prophylactic third molar removal.

The National Institute for Health and Clinical Excellence (NICE) is an independent organization in the UK established by the government to encourage evidence-based practice in medicine and to produce guidance on treatment and care of people with specific diseases and conditions within the NHS. In 2000 NICE published a "Guidance on the Extraction of Wisdom Teeth" with recommendations that are more or less in line with the criteria from the NIH consensus conference in 1979.⁹⁰ Summing up these two publications produces a list of appropriate indications for third molar removal:

- recurrent or severe pericoronitis;
- periodontal disease with a pocket depth of 5 mm or more distal to the second molar;
- non-restorable caries in the third molar;
- resorption of the third molar or adjacent tooth;
- caries in the second molar where the third molar removal would render restoration possible or more simple;
- apical periodontitis;
- cysts or tumors associated with the third molar (or adjacent tooth);
- when required for orthognatic surgery;
- removal of third molar in a fracture line.

While the NICE guidance clearly states that "*the practice of prophylactic removal of pathology-free impacted third molars should be discontinued in the NHS*", it was agreed in the NIH conference, "*after lengthy discussion*", that impaction or malposition of a third molar is an abnormal state and *may* justify its removal. These two documents present a slightly different view on whether a single episode of pericoronitis is appropriate indication for third molar removal. The NIH conference was in favor of referring to the well known "potential for repetitive infection and morbidity". From a patient perspective, Slade *et al.*⁹¹ noted that 37% of 480 patients who had pain or swelling

indicating an episode of pericoronitis 3 months before surgery, found the symptoms sufficient to seek surgical expertise for third molar removal before the symptoms recurred. This clearly emphasizes the importance of an open dialog between patients and dentists/oral surgeons where patients' preferences can be evaluated and the clinician presents his or her judgement of the benefits and risks for removal or retention for that particular third molar. One should also remember that a document such as the NICE publication is guidance, and as it is stated in this paper the guidance "*does not, however, override the individual responsibility of health professionals to make the appropriate decisions in the circumstances of the individual patient, in consultation with the patient and/or guardian/carer*". Guidelines for health care procedures are at their best an evidence-based view of eminent scientists and clinicians at a certain time and will thus form an excellent basis for ethical practice. However, new research findings, new treatment options, changes in patients' preferences, and changes in resources allocated to health care require that clinical guidelines be reviewed and updated regularly.

Prophylactic third molar removal

Prophylactic removal of a non-erupted tooth is by definition a surgical intervention to prevent future disease. This practice is often referred to as "removal of asymptomatic third molars". It is important to define this subject more precisely. A *symptom* is defined as an indication of a disease noticed by a *patient*, such as pain, swelling, restricted mouth opening, foeter ex ore, difficulty in chewing or swallowing food or drink. *Clinical signs* are observations by a *health professional* indicating a disease or disorder such as bleeding on probing, pathologic pocket depth, tenderness on palpation, and radiographic signs of pathology. Thus, it is obvious that a patient can present with an asymptomatic third molar but with clinical signs of pathology. It is not uncommon that a third molar completely impacted in bone and associated with a follicular cyst can be totally asymptomatic to the patient (Figs 13.6, 13.7). There is, however, no controversy in the professional recommendation for surgical removal of a third molar with clinical signs of disease even if this molar is asymptomatic to the patient. Surgery on such indications is regarded as therapeutic. What prophylactic surgery specifically refers to is the removal of asymptomatic and pathology-free non-erupted or impacted third molars. In other words, the indication for surgical removal in such circumstances is the mere presence of a non-erupted or impacted third molar even if not associated with pathology.

The practice of prophylactic third molar removals that emerged in the middle of the 20th century was almost universally accepted in the industrialized world. This concept was the leading norm, or gold standard, for treatment of impacted third molars in

Fig. 13.6 Sixteen-year-old male examined with a panoramic radiograph (a) as part of a preorthodontic evaluation. There were no subjective symptoms and no extra- or intraoral findings suggesting the presence of this cystic lesion. The histopathologic examination (b) revealed an odontogenic keratocyst. The patient was followed radiographically for 6 years without any signs of recurrence.

textbooks on oral and maxillofacial surgery. As a good example of this view, Larry J. Peterson stated as late as 1998⁹² that, “If impacted teeth are left in the alveolar process, it is highly probable that one or more of several problems will result. To prevent this, impacted teeth should be removed.” He then argues, using radiographic illustrations, that third molar removal can prevent periodontal disease, dental caries, pericoronitis, root resorption, odontogenic cysts and tumors, and fractures of the jaw. Third molar removal is also indicated to facilitate orthodontic treatment and in some cases of unexplained pain in the retromolar region of the mandible. Furthermore, impacted teeth in areas later to be restored with a prosthodontic appliance should be removed before such treatment is performed.

Recent research on the “third molar problem” has focused on periodontal problems related to the retention of third molars. A research team headed by Raymond P. White and supported by the American Association of Oral and Maxillofacial Surgeons in

concert with the Oral and Maxillofacial Surgery Foundation has made a progress report on a very ambitious and comprehensive project called “Third Molar Clinical Trials”.⁹³ They have enrolled 356 patients for a longitudinal study with a follow-up time of at least 4 years. The median age at inclusion was 26 years and it was required that the subjects have no third molar symptoms at enrolment. From their preliminary data, they conclude that a considerable number of young adults documented substantial periodontal pathology affecting the third molar region. They also conclude that “data from the subjects followed over time suggest that in a considerable number of young adults, periodontal pathology initiates in the mandibular region, spreads forward in the lower jaw, up to the third molar region of the maxilla, and subsequently forward in that jaw”. One of their conclusions also suggests that third molar periodontal pathology is a major contributor to chronic oral inflammation with a potential for a systemic inflammatory response with

Fig. 13.7 Panoramic radiograph of a 64-year-old female. A follicular cyst was found in association with the impacted left mandibular third molar. There was no subjective or clinical finding in relation to this finding. Her other three third molars were totally impacted covered by bone and/or soft tissue, asymptomatic, and pathology-free. Only the left mandibular third molar with its associated cyst was treated surgically.

possible negative effect on cardiovascular and obstetric health outcomes. To a great extent based on these Third Molar Trials, Assael,⁹⁴ in an editorial in 2005, concludes that *“all third molars should be considered for removal in young adults in order to mitigate the risks of systemic inflammation and local progression of emergent periodontal disease”* and that patients with retained third molars *“should be informed of research regarding increased risks for systemic disease”*. One should, however, remember that patients, including young adults, with evidence of periodontal disease (pathologic pockets >4mm) in their third molar region have an accepted therapeutic indication for surgery. The treatment and prevention of periodontal problems in other regions of the jaws is of course the responsibility of their GDP.

In the last 20–25 years the practice of prophylactic third molar removal has been questioned for several reasons. Public health experts have questioned the effectiveness of allocating limited health care resources to preventive surgery. Data from decision analysis as well as from studies on patients' preferences suggest that prophylactic third molar surgery is not an appropriate procedure. Those studies have been reviewed earlier in this chapter. To this, an ethical dilemma can be added. If we admit that removal of an asymptomatic pathology-free third molar eliminates possible risks for future disease, we also have to acknowledge that such a procedure has its costs, and so also has a non-surgical management with intentional retention of the third molar. The costs for surgery include not only direct and indirect monetary costs as reviewed earlier, but also individual personal costs of postoperative disability, influence on social life, time lost from work or studies, and complications, both temporary and permanent. The costs for intentional retention of a third molar are the monetary costs for regular dental check-ups which of course also must include the third molar region, costs for removal should pathology eventually be diagnosed, and individual costs for disability related to symptoms from the disease. From an ethical point of view, it is reasonable to suggest that an invasive procedure with certain well known risks on an asymptomatic pathology-free condition requires stronger evidence than performing the same intervention with the same risks when a disease is finally diagnosed. Furthermore, it is also probably easier for a patient to accept a permanent complication or disability of an intervention if it was based on a therapeutic indication than if surgery was performed to prevent a possible disease.

Systematic reviews and guidelines

The appropriateness of prophylactic third molar removals has been assessed by independent health care organizations as well as professional associations. The number of reviews and guidelines published during the last 10–15 years confirms the impact

of third molar management as an important public health item. In the early 1990s Ben Toth¹⁸ at the Health Care Evaluation Unit at the University of Bristol summarized a literature survey stating that *“on the basis of these studies it is concluded that prophylactic surgery is not an appropriate management strategy for asymptomatic impacted third molars”*.

In 1999 the Scottish Intercollegiate Guidelines Network (SIGN) published an important and comprehensive national clinical guideline on the *“Management of Unerupted and Impacted Third Molar Teeth”*.⁹⁵ Although not specifically addressing the subject of prophylactic third molar removals, there are several statements in this document that contradict prophylactic surgery. Referring to third molars completely covered by soft tissue and/or bone and without evidence of pathology, the recommendation is to leave these teeth *in situ*. The NICE guidelines from 2000⁹⁰ are very clear in their recommendation that *“the practice of prophylactic removal of pathology-free third molars should be discontinued in the NHS”*.

Song *et al.*⁹⁶ from the NHS Centre for Reviews and Dissemination, University of York, UK, published a report in 2000 based on an extensive literature survey where published articles were assessed according to inclusion criteria on their scientific evidence (for review, see Goodman⁹⁷). From more than 4500 references of possible relevance, they examined 290 papers and finally included 40 studies in their review: two RCTs (randomized controlled studies), 24 literature reviews, and four decision analysis studies. They conclude that *“there is no reliable research evidence to support the prophylactic removal of disease-free impacted third molars. Available evidence suggests that retention may be more effective and cost effective than prophylactic removal, at least in the short to medium term.”*

The 2003 report on prophylactic third molar surgery from a Norwegian national center for health technology assessment, SMM,⁹⁸ emphasizes that the evidence is based on studies that use small selected patient groups and it is therefore difficult to give recommendations. The authors conclude, however, that *“Norwegian dentists recommend prophylactic removal of third molars when the likelihood of third molars causing problems in the future is high and the incidence of postoperative complications is low. This includes partially erupted wisdom teeth. Removal of asymptomatic fully retained wisdom teeth is not recommended.”*

The Cochrane Collaboration is an independent global network aiming to improve health care decisions through evidence-based systematic reviews. As part of this network, Mettes *et al.*⁹⁹ published a review on *“Interventions for treating asymptomatic impacted wisdom teeth in adolescents and adults”* in 2005. They selected all randomized or controlled clinical trials comparing the outcome of prophylactic removal of third molars versus their retention (no treatment). They found only three publications that satisfied their inclusion criteria and found no evidence to support

or refute routine prophylactic removal of asymptomatic third molars in adults. On the other hand, there is some reliable evidence that removal of asymptomatic third molars in adolescents neither reduces nor prevents late incisor crowding.

In a statement by the American Association of Oral and Maxillofacial Surgeons in 2007 concerning “The management of impacted third molar teeth”¹⁰⁰ there are several arguments supporting the removal of asymptomatic non-erupted third molars. The document states that “*aside from obvious indications for removal of impacted teeth such as overt pathology, removal is also the preferred option for teeth if there is insufficient anatomic space to accommodate normal eruption*” and that “*removal of such impacted third molar teeth at an early age is a valid and scientifically sound treatment rationale based on medical necessity*”.

It is evident that there are geographical differences in how dental professionals judge the scientific base for or against prophylactic third molar removals. While oral and maxillofacial surgeons in the US generally recommend patients to routinely have their third molars removed prophylactically, their colleagues in many European countries discourage their patients from having impacted pathology-free third molars removed. This may reflect differences in the health care systems, in the available manpower of surgical specialists in dentistry, but also differences in the interpretation of risks and benefits for individual patients and the need to assess priorities in a limited health care economy.

From the literature on the natural history of third molars referred to earlier, it is obvious that not all non-erupted or impacted third molars run the same risk of developing pathology. When patients ask for guidance whether or not to remove an asymptomatic pathology-free third molar it is important to present a realistic assessment of the risk for the individual third

Table 13.7 The scores from the eight variables in Table 13.6 are added together and form the “Risk Index M3”. The table indicates the level of risk with an index score ranging from 0 to 8. Of clinical importance is that the higher the score, the higher is the risk of a deep intrabony defect subsequent to third molar removal. From Kugelberg *et al.*^{101,102} Copyright © 1991 Elsevier.

Risk Index M3	Index score
No risk	≤1
Low risk	2
Moderate risk	3
High risk	≥4

molar in question. Implementing the facts on third molar-related disease prevalence one can conclude that:

- Third molars with complete root formation and totally covered by bone tissue are associated with a very limited risk for development of pathology and can thus be retained.
- Third molars partially covered by soft tissue have different risk for pathology depending on their position. A vertical or distoangular position presents a higher risk for development of associated pathology than other positions.^{28,50}
- There is no evidence at present of a significant increase of third molar-associated pathology with age.^{38,47}
- Periodontal problems on the distal surface of the second molar can result both from retaining or removing a third molar as has been shown by Kugelberg *et al.*^{101,102} The Risk Index M3 as designed by Kugelberg (Tables 13.6, 13.7) can serve as guidance when discussing the indication for third molar removal with patients at risk of remaining periodontal bone defects. An index score of 3–4 rather indicates a therapeutic indication as earlier described than a prophylactic approach.

Table 13.6 Variables included in Kugelberg’s Risk Index M3. From Kugelberg *et al.*^{101,102} Copyright © 1991 Elsevier.

Variable name	Symbol	Classification	Value
Preoperative plaque index (second molar distal)	(PLI)	Not visible Visible	0 1
Preoperative probing depth (second molar distal)	(PD)	≤6 mm >6 mm	0 1
Preoperative intrabony defect (second molar distal)	(IBDP)	≤3 mm >3 mm	0 1
Sagittal inclination third molar	(INCL)	≤50° >50°	0 1
Contact area second and third molar	(AREA)	Small contact Large contact	0 1
Resorption distal root of second molar	(RESO)	No Yes	0 1
Pathologically widened follicle of third molar	(FOLL)	No or distal Mesial ≥2.5 mm	0 1
Smoking habits	(CLG)	Non-smoker Smoker	0 1

Medical and surgical indications for prophylactic third molar removal

There are certain medical and surgical conditions or situations when removal of an asymptomatic pathology-free third molar is an appropriate treatment. Most of these indications are relatively uncommon and, although there is a general agreement on some of these interventions, others represent relative indications. In oral and maxillofacial surgery such indications are:

- the presence of a third molar in a fracture line;
- prior to orthognatic surgery;
- when a third molar may be considered for autogenous transplantation, usually to a first molar region;
- when the third molar region is involved in tumor resection or jaw reconstruction surgery.

Medical conditions that require a serious consideration of prophylactic third molar removals are:

- prior to radiation therapy for head and neck malignancies;
- prior to organ transplantation;
- chemotherapy;
- bisphosphonate therapy.

The indication for prophylactic removal is especially relevant for third molars partially or totally covered by soft tissue. The strength of the indication in those situations is often discussed in cooperation with the physician responsible for the treatment of the medical condition, but the oral and maxillofacial surgeon, however, must have a great impact on risk assessment and the decision on whether to remove or retain the third molar(s).

For 5–6 years, data has been accumulating on a rare but serious complication of bisphosphonate therapy. Our present knowledge of this condition – bisphosphonate-induced osteonecrosis of the jaws – has recently been presented by Robert E. Marx.¹⁰³ The complication presents clinically as exposed necrotic alveolar bone in the mandible or maxilla for more than 8 weeks in a patient who has taken or currently is taking bisphosphonate medication. There should be no history of radiation therapy to the maxillofacial region. The risk for developing this side-effect of the drug is correlated with its administrative route. Intravenous administration of bisphosphonates, usually prescribed for bone metastasis from breast cancer or multiple myeloma, results in a much faster accumulation in bone in contrast to the oral administration of bisphosphonates where the primary indication is treatment of osteoporosis. A high number of osteonecrotic complications (75%) develops as a result of surgical dental trauma or uncontrolled odontogenic inflammatory diseases so it is recommended that medical oncologists refer all patients with an indication for intravenous bisphosphonate therapy to an experienced dentist or an oral and maxillofacial surgeon for consultation. Dental treatments that are invasive in character, and are deemed necessary for control of odontogenic infections, such as tooth extractions or periodontal therapy, should be performed before the start of intravenous bisphosphonate therapy. That includes a recommendation of removal of non-erupted third molars with oral communication.

For patients taking oral bisphosphonates the accumulation rate in bone tissue is much slower, and there is evidence that oral surgical procedures like tooth removals, sinus augmentation grafts, and implant placements can be performed if the patient has taken this medication for less than 3 years. For patients with a regular use of oral bisphosphonates for a period longer than 3 years, there is a steady increase for risk of osteonecrosis of the jaws following invasive dental procedures with the length of use. For this group of

patients a judgement of the need for prophylactic removal of non-erupted third molars with oral communication should be made during the first 3 years of medication.

Complications associated with third molar surgery

As with all surgical procedures there is a risk for operative or postoperative complications when an impacted third molar is surgically removed. In any elective intervention the judged benefit, both in a short- and a long-term perspective, must be outweighed by the consequences of estimated complications. Besides the impact on social life, work, and studies, as well as on oral function as described earlier in this chapter, there is a number of transient or permanent complications after third molar surgery that should be considered. The prevalence, prevention, and treatment of those complications is covered elsewhere in this book (Chapter 14). There is an extensive literature on complications following third molar removal. A summary of frequencies reported in the last 20–30 years as reviewed by Liedholm¹⁰⁴ indicates the following possible complication rate:

- postoperative alveolitis 0.5–32.5%;
- postoperative infection 0.9–4.2%;
- postoperative bleeding 0.2–1.5%;
- transient dysfunction of the inferior alveolar nerve 0.6–5.5%;
- permanent dysfunction of the inferior alveolar nerve 0.1–0.9%;
- transient dysfunction of the lingual nerve 0.004–11.5%;
- permanent dysfunction of the lingual nerve 0.2–0.6%.

When giving advice to a patient whether or not to have a third molar removed, the surgeon must inform the patient of his or her judgement of risks associated with the particular third molar in question. There are several factors to consider when such a risk assessment is made. The age of the patient, his or her medical history, the degree of impaction and angular position, as well as the relation of the third molar roots to anatomical structures, such as the inferior alveolar nerve, are all factors that may influence the risk for complications associated with third molar removal. Thus, the information of operative risks must be adapted to the individual third molar, e.g. the slightly mesoangular third molar partially covered by soft tissue and with a short conical root presents a lower risk for complications than a horizontally deep bone-impacted third molar with divergent roots with the mandibular canal in close proximity to the roots. When a patient considers the benefits of prophylactically removing an asymptomatic pathology-free third molar it is especially important to make sure that this patient comprehends the

Fig. 13.8 Panoramic radiograph of a woman at age 56 years. The right mandibular third molar is totally covered by bone, asymptomatic, and without associated pathology. The decided strategy was a long-term observation.

Fig. 13.9 Panoramic radiograph of the same person as in Fig. 13.8, now at age 63. A follicular cyst has developed during these 7 years, now indicating removal of the impacted third molar and a cystectomy.

judged risks for complications. It may also be relevant to inform the patient that in a number of professional reviews and guidelines this indication for third molar removal is discouraged. Furthermore, studying patients' preferences about third molar surgery, patients ranked the described outcomes of non-removal higher than those outcomes describing the outcomes of removal.

Contraindications for third molar removal

As a general rule, no teeth should be removed without an appropriate indication. Summarizing our current knowledge on the natural history of third molar impaction and professional judgement published in reviews and guidelines it is recommended that:

- Third molar buds in young people should not be enucleated.
- Asymptomatic and pathology-free third molars totally covered by bone should not be removed.
- Routine removal of asymptomatic pathology-free third molars totally or partially covered by soft tissue is not recommended. Specific medical and surgical conditions as well as a high index score on

the Kugelberg Risk Index M3 may prove a prophylactic approach appropriate.

- Third molar surgery is contraindicated in patients whose medical history or conditions expose the patient to an unacceptable risk to their overall health.

When an impacted third molar is diagnosed and a decision is made to retain that molar, the patient should be informed of the reason for non-intervention. Regular examination of that third molar to check the development of possible pathology should be recommended (Figs 13.8, 13.9).

Chapter 14

Surgical Management of Third Molars

Tara Renton

Third molar removal is one of the most common surgical procedures worldwide. This chapter provides an overview of presurgical assessment and management and describes principles for the surgical management. The intention of this chapter is to provide some useful assessment and surgical tips for use in third molar surgery. It is also a specific aim to introduce the idea of minimal access third molar surgery in order to minimize trigeminal nerve injuries where possible. Coronectomy is discussed as a viable alternative to tooth removal in high-risk third molar teeth.

Introduction

The failure of eruption of third molars is a very common condition.^{1–3} Extraction of impacted third molar teeth is one of the most frequent surgical procedures carried out in the National Health Service (NHS) in the UK.³ It has been reported that a significant proportion of those on oral surgery waiting lists are awaiting third molar removal.^{2,3}

Removal of third molars remains the “mainstay” of activity for oral surgery. Third molar surgery has been one of the ten most common procedures undertaken in the NHS and the cost of removing wisdom teeth in the UK has been calculated to be in the region of £50 million per annum, although this figure may well have decreased significantly since the publication of guidelines by the National Institute for Health and Clinical Excellence.⁴ Conversely over 95% of oral surgeons in the USA regularly undertake prophylactic third molar surgery.⁵ As a profession we must be cognizant of various geographical differences in oral surgical practice as the pressure and outcomes will vary accordingly. Third molar surgery (TMS) is a source of considerable income for some surgeons.⁶ It comprises the main costs for some USA insurance companies^{6,7} and for all those involved TMS provides a daily challenge in patient care provision. Guidelines for the indications for third molar surgery are discussed in Chapter 13.

Surgical procedures for extraction of third molar teeth are associated with significant morbidity. These include expected sequelae, including pain and swelling, and potential complications, including temporary or permanent nerve damage, resulting in permanent numbness, pain or altered sensation of lip or tongue.⁸ There appears to be substantial variation in management of third molars and it has been reported that conservative treatment with more rigorous adherence to specific indicators for removal would reduce surgical cases by up to 60%.⁹ A recent review by the NHS Centre for Reviews and Dissemination¹⁰ concluded that “*there appears to be little justification for the removal of pathology-free impact-*

ed third molars". However in the USA prophylactic removal of third molars is routine⁶ and debate continues on this practice.^{6,7,9,11–13} Despite this transatlantic difference a consensus exists that the keys to successful surgery are good training, planning, patient selection, and care provision (preoperative, operative, and postoperative). The main complications related to third molar surgery are alveolar osteitis (fibrinolytic alveolitis, dry socket) and temporary or permanent nerve injury.¹⁴ These injuries often cause permanent neuropathic pain in and around the mouth, resulting in significant difficulties for the patient with regard to eating, drinking, speaking, kissing, shaving, applying makeup, and often sleeping (just about every social interaction we take for granted). As a result lingual and inferior alveolar nerve injuries remain one of the main causes of litigation related to dentistry, often resulting in significant financial compensation depending on the country and legal system. Prevention of these injuries must be foremost in the surgeon's mind when planning this type of surgery. This section aims to provide a basic framework and useful tips for third molar surgery.

Definitions and terminology

For the purposes of this chapter guideline, minor modifications of previously reported definitions^{1,5,8,9} have been introduced:

- An unerupted tooth is a tooth lying within the jaw bone, entirely covered by soft tissue, and partially or completely covered by bone.
- A partially erupted tooth is a tooth that has failed to erupt fully into a normal position. The term implies that the tooth is partly visible or in communication with the oral cavity. Pericoronitis, the most common indication for removal of third molars, can only occur if the tooth is partially erupted and in communication with the mouth.
- An impacted tooth is a tooth which is prevented from completely erupting into a normal functional position. This may be due to lack of space, obstruction by another tooth, or an abnormal eruption path. The tooth may be soft tissue impacted or hard tissue impacted (bone or adjacent tooth) and may be unerupted or partially erupted. Impaction per se is NOT an indication for removal, it is a clinical description of the position of the tooth.

Throughout this chapter the term **third molar** refers to a partially erupted third molar tooth which may or may not be impacted. In general the term applies to both **upper** and **lower** third molar teeth, but surgical management of upper third molars is generally simpler compared to that of lower third molars. Upper wisdom teeth cause less discomfort, are more likely to erupt, and are simpler to remove unless unerupted and encased in bone (when perhaps removal is not

indicated). Removal of upper third molars results in far less postoperative morbidity.

Presurgical assessment of third molars

Clinical assessment

Clinical assessment should be carried out with the aim of assessing the status of the patient and their third molars and excluding other causes of the symptoms. Initial assessment should include:

- patient complaint;
- patient age;
- social history;
- a full medical history;
- a full dental history;
- extraoral clinical examination;
- intraoral clinical examination.

Positive findings from this examination, which suggest that treatment of the third molar or related structures may be indicated, require that a more detailed examination is carried out. This should determine whether removal is indicated and/or advisable (see Chapter 13) and should include radiological assessment.

A complete examination should include assessment of:

- willingness and ability of the patient to cooperate with care;
- the eruption status of the third molar (Figs 14.1, 14.2);
- caries in, or resorption of, the third molar and the adjacent tooth;
- periodontal status (Fig. 14.3);
- occlusal relationship;
- temporomandibular joint function (identify existing limited access or pain which may be exacerbated by third molar surgery);
- mouth opening, as trismus will hinder access for surgery;
- regional lymph nodes;
- any associated pathology.

Radiological assessment

The purpose of a careful radiological evaluation is to complement the clinical examination by providing additional information about the third molar, the related teeth and anatomic features, and the surrounding bone. This is necessary in order to make a sound decision about the proposed surgical procedure, the most appropriate location for this to take place, and to highlight aspects of management which may require specific discussion with the patient.

Fig. 14.1 Clinical photograph of partially erupted lower left molar with no local inflammation.

Fig. 14.2 Clinical photograph of partially erupted lower left with acute pericoronitis of 38. Notice the "imprint" of 28 occlusal surface.

Fig. 14.3 An overerupted upper 28 with periodontal disease.

Prior to the age of 13, radiographic examination is not normally indicated for the assessment of third molars¹⁵ and films taken from the age of 20 are most useful in assessing the likelihood of eruption.¹⁶ When more than one third molar requires assessment, the radiographic examination of choice is a panoramic radiograph as the radiation dose of a panoramic radiograph is lower than from four periapical views and the diagnostic yield is higher.¹⁷⁻¹⁹ Doses from panoramic radiography can be further limited by using field size limitation to prevent exposing areas not required in the field of view.²⁶ Periapical or oblique lateral radiographs may be taken as an alternative. All radiographs should be of a diagnostically acceptable standard.^{19,20}

The effectiveness of axial computed tomography (CT) with coronal and sagittal reformatting in establishing the three-dimensional relationship of the inferior alveolar nerve (IAN) and the third molar has been shown.²¹⁻²³ CT permits: localization of the IAN canal in the superior-inferior and mediolateral positions; detection of an intraradicular path; determination of the distance between the tooth and IAN canal; and root angulation. In the setting of high-risk findings on the panoramic radiograph where the mandibular third molar requires removal, CT can provide valuable information to facilitate management.²³ If the IAN is entrapped within the substance of the tooth, coronectomy or monitoring may be indicated. Knowing the IAN canal position relative to the third molar may decrease the frequency or severity of IAN injury.

Overall the combined clinical and radiologic assessment of third molars is intended to enable the clinician to make a diagnosis which may be concordant with indications for removal of the tooth leading to surgical planning. Factors that are important in planning the surgical approach are shown in Table 14.1.

Application depth

The alveolar bone level and tooth position will dictate the application depth (Fig. 14.4). The depth of applica-

tion and the point of elevation will dictate the amount of bone removal that is required to gain access to the optimal application point. This factor is the most predictive of difficulty of surgery.^{24–26}

Table 14.1 Dental factors that may be important in planning surgery.

Factor	Illustration
Depth impaction	Fig. 14.4

The relationship or proximity of upper third molars to the maxillary antrum and of lower third molars to the inferior dental canal	Fig. 14.17

Angulation

The distinction between vertical, mesoangular, horizontal, and disto-angular orientation may affect the surgical approach, in particular with regard to the requirements for bone removal in order to gain access to point of application. These positions have been classified by Archer (1975).²⁷ The incidence of the position of the tooth is:

- Vertical impaction: 40% of all impacted mandibular third molars and usually the least difficult to remove.
- Mesoangular impaction: 45% – can be of moderate difficulty.
- Horizontal impaction: 10% – are generally of intermediate difficulty.
- Distoangular: 5% – the most difficult to extract and frequently underestimated.

The application point is not only dictated by the angulation of the tooth but also root morphology and proximity to adjacent structures (adjacent tooth, antrum, and nerve). In association with identifying the tooth angulation, the potential space for application points must be identified. Often distoangular lower third molars are in close proximity to the adjacent 7 and have limited space for mesial application point. Several examples of radiographs of third molars illustrating angulation of teeth and a summary of potential application points and planned sectioning are provided in Figs 14.4 and 14.5.

Fig. 14.4 Diagram of application point depth. How is this measured? From the alveolar ridge to the point of application on the tooth. This will vary depending on the depth and angulation of the tooth. (a) Vertical; (b) mesoangular; (c) distoangular; (d) horizontal. Red line indicates application depth (mm); red dot indicates the application point. The length of the red line indicates the necessary vertical bone removal to reach the application point. (e) Key application points for each angulation: (i) vertical – mid-buccal; (ii) mesoangular – meso-buccal; (iii) distoangular – buccal/disto-buccal; (iv) horizontal – buccal.

Fig. 14.5 The orientation of the tooth and the proximity to the adjacent tooth are important to assess, particularly with regard to distinction between vertical and distoangular orientation which may affect the requirements for bone removal. (a) Maxillary buccally erupted mesoangular 28 with no application space distal to 27. (b) Maxillary buccally partially erupted impacted distoangular 28. (c) Mandibular non-impacted erupted 48 in vertical position. (d) Vertical position, soft tissue impacted, partially erupted 48 with evidence of chronic inflammation with distal bone loss. (e) Vertical position, unerupted, bone impacted. (f) Horizontal position, partially erupted, tooth impacted. (g) Horizontal position, unerupted with oral communication. (h) Horizontal, unerupted below bone, no oral communication. (i) Mesoangular position, partially erupted, tooth impacted. (j) Distoangular, partially erupted, bone impacted. Diagrammatic summary of tooth angulation: classification of impaction of (k) maxillary third molars and (l) mandibular third molars (according to Archer, 1975²⁷): 1, mesoangular; 2, distoangular; 3, vertical; 4, horizontal; 5, bucco-angular; 6, linguo-angular; 7, inverted.

Fig. 14.6 Size of the crown. (a) Diagram of measurement of crown width. Red line drawn across maximum width of crown. If this is more than bony window in alveolar ridge (black line) then crown section will be indicated. (b) Crown wide. Wide crown width will increase surgical difficulty. (c) The crown condition – caries. (d) Gross caries of 38. (e) Crown heavily restored.

The crown size and condition

The crown width of the third molar can be an important factor in making surgery more difficult. If the tooth is impacted and the crown is wide, sectioning of the crown will be required to minimize bone removal thus reducing potential pain and swelling for the patient. If the third molar is carious or heavily restored or indeed non-vital, this may render the tooth more brittle on elevation thus impacting on surgical difficulty. See Fig. 14.6.

Distance across roots is larger than width of crown–root junction

If the root width is greater than the width of the tooth at the alveolar crest, the difficulty of surgery will increase and root sectioning will be indicated (Fig. 14.7). Multiple roots or hooked roots will also contribute to surgical difficulty and are more commonly seen in certain ethnic groups. Hypercementosis or ankylosis of third molar roots will also increase surgical difficulty and must be identified on radiographic evaluation.

Fig. 14.7 (a) Diagram of measurement of root width. (i) Roots convergent when root maximum width is less than that of the crown base. (ii) Roots divergent when maximum root width is greater than base of crown (indication of increased difficulty of surgery and probable root section). (b) (i and ii) Splayed roots. Distance across roots is larger than width of crown root junction. (c) Lower third molar with four splayed roots.

Root number and morphology

More complex root morphology is associated with increased difficulty of surgery (Fig. 14.8).²⁸ Identification of such hooks is important, as they may fracture during removal of the tooth and a decision is then

Fig. 14.8 (a) Conical/convergent roots. (b) Club-shaped roots. (c) Bifid roots. (d) Bifid divergent roots. (e) Multiple roots (may be penetrating lingual plate).

required as to whether to attempt their removal. Hooked, dancing or bent roots may provide a “challenge” to routine elevation. Even after sectioning of the crown and roots, if the root morphology is complex the roots will often require further sectioning and patience is often required to identify the “sweet spot” with which the resistant root will comply with elevation.

Occasionally lower third molar roots can perforate the lingual plate and this is often not evident until part way through surgery. Every effort must be made to ensure these roots do not get lost through the perforated lingual plate, one of the rare indications to raise a lingual flap for third molar surgery.

Root surface area

Assessment of the relative root surface area of the tooth to be extracted and the adjacent tooth must be estimated (Fig. 14.9). If the third molar is multirrooted adjacent to a conical root lower 7, the lower 7 is more easily mobilized during elevation of the 8. If the root surface area of the adjacent tooth is significantly less than that of the intended extractee then the surgical approach must be adjusted accordingly to prevent any undue application of pressure near the adjacent tooth.

If the adjacent tooth is subluxated it should be immediately replaced and a figure-of-eight suture placed across the occlusal surface to “restrain” the tooth. Antibiotics and oral hygiene should be initiated, and, of course, the patient advised.

Follicular width

There is no substantive evidence as to the dimension of follicular space which clearly indicates that cystic change has taken place.^{29,30} Where doubt exists as to the likelihood of cystic change and there are no other positive indications for removal of the tooth, radiological review at between 6 and 12 months is the recommended course of action.

An enlarged follicle is usually considered to be non-cystic where the diameter is less than 1 cm. Radiographic radiolucency adjacent to the crown of a partially erupted third molar may be due to a

Fig. 14.9 Root surface area depends on length, width and number of roots. (a) Root surface area of 8 less than that of 7. (b) Root surface area of 8 greater than that of 7 (risk of displacing 7 on mesial application to 8).

Fig. 14.10 Radiographic radiolucency adjacent to the crown of an impacted third molar may be due to enlarged follicle.

previously enlarged follicle or chronic local infection (Fig. 14.10).

Pathology associated with third molars

Cysts are the most common pathology associated with mandibular third molars. If the cyst is associated with the crown of the tooth, the first differential diagnosis should be dentigerous cyst followed by keratocyst or ameloblastoma. Keratocysts are more likely to be associated with missing teeth. Surgical removal of third molars in association with pathology may be facilitated. However the surgeon must ensure the pathology is correctly diagnosed and treated accordingly. Some examples of cysts associated with third molars are shown in Fig. 14.11.

Periodontal status

The periodontal status of the adjacent tooth and that of the third molar (Fig. 14.12) will influence surgery. Bone loss due to periodontal disease will often facilitate the removal of the third molar tooth but care must be taken to prevent inadvertent removal of the periodontally involved 7.

The restorative condition of the adjacent 7

If the adjacent tooth to the third molar is carious or heavily restored or indeed non-vital (Fig. 14.13), this may render the tooth more brittle and more at risk of damage on elevation of the third molar, thus impacting on surgical difficulty. It is important that the patient is warned of possible damage to the adjacent 7 during surgery.

Proximity to the inferior alveolar canal

There are several radiographic signs assessed on panoramic radiographs that are associated with an increased risk for IAN injury (Fig. 14.14).^{26,31–36}

Fig. 14.11 Cystic lesions associated with third molar teeth. (a) Paradontal cyst associated with 38. (b) Monocystic lesions associated with crown of mandibular third molar likely to be a dentigerous cyst but could be mimicked by keratocyst. (c) Multicystic lesion associated with impacted 38. This proved to be an ameloblastoma.

Fig. 14.12 The periodontal status of 48 is severe.

Fig. 14.13 (a) Restorative condition of adjacent 7 non-vital and crowned. (b) Heavily restored 47. (c) Caries distal surface of 47. (d) It is possible to excavate distal caries in the distocervical region of 37 whilst removing 48. (e) Restoration undertaken during removal of the mandibular third molar.

Fig. 14.14 (a) Superimposition of the IAN canal and third molar. (b) Diversion of the IAN canal. (c) Darkening of the root where it is crossed by the canal and widening of canal. (d) Interruption of the white lines of the canal. (e) Darkening of roots with associated widening of the canal. (f) Juxta apical area. This apical area on a vital third molar may reflect a confluence of the periodontal membrane and the IAN canal; however thus far neither CT nor MRI scan have been able to detect specific cavities. This radiographic feature was the main radiological risk factor for IAN injury.²⁶

Cone-beam CT scanning

Cone-beam CT (CBCT) scanning for mandibular third molars is indicated if on the initial panoramic radiograph, there is a suggestion of a relationship between the roots of the lower third molar and the IAN canal. This is a relatively new technique and caution is required to only use this additional scanning when the lower third molar is found to cross the IAN canal on plain films. It will be interesting to see how CBCT scanning will influence surgery. For many surgeons, high-risk vital third molars are planned for coronectomy and CBCT will not alter the planned surgery in these cases. However if the high-risk third molar is non-vital or the patient requests removal of

the third molar, CBCT scanning may assist the surgeon in planning surgery depending on the relationship of the IAN canal and the tooth. Examples of lingual and buccal relationship of the IAN to the lower third molar tooth are shown in Fig. 14.15.

The sensitivity and specificity of CT imaging to panoramic imaging in predicting IAN exposure at the time of third molar removal was 70 and 63% respectively.²² This suggests that in the absence of any high-risk findings on panoramic radiograph, the risk for IAN injury is unlikely and has a high negative predictive value (>90%). Other studies have reported that the presence of two or more radiographic signs, depth of impaction, and horizontal angulation were

Fig. 14.15 Cone-beam CT (CBCT) scan of lower third molar. (a) CBCT section illustrating close proximity of IAN to the third molar tooth root on the lingual aspect. (b) CBCT section illustrating distant proximity of IAN to the third molar tooth root on the buccal aspect.

associated with an intimate anatomic contact between the third molar and IAN canal on CT.³⁶ Likewise another study noted several clinical and panoramic radiographic predictors associated with an increased risk for IAN injury.³⁷ For the CT findings, the sensitivity and specificity were 93 and 77%, respectively. In another study similar findings were noted with the surgeon's prediction of IAN injury on reviewing the panoramic radiograph to have a sensitivity of 72% and specificity of 91%.³⁵ The American Association of Oral and Maxillofacial Surgeons (AAOMS) White Paper⁵ concludes that the exact role and indications for CT imaging for the management of impacted third molars is unclear and evolving. In the presence of any of the above findings the decision to treat should be carefully reviewed. The patient should be advised of the increased risk (20% temporary or 2% permanent IAN injury). Alternative surgical tech-

niques may be indicated (coronectomy of the tooth if vital, splitting of the roots if multirrooted).

Atrophic mandible or very long roots of third molar

Exceedingly long roots or atrophic mandible may place the patient at higher risk of mandibular fracture during removal of the lower 8 (Fig. 14.16).

Proximity of other structures

The relationship or proximity of upper third molars to the maxillary antrum and of lower third molars to the IAN canal should be assessed (Fig. 14.17).

Fig. 14.16 Exceedingly long roots or atrophic mandible may place the patient at higher risk of mandibular fracture during removal of 38.

Fig. 14.17 The relationship or proximity of third molars to the adjacent unerupted teeth. Maxillary antrum to 18 and 48 and 19 to the inferior dental canal.

Risk assessment

Evaluating the difficulty of third molars has been the aspiration of many authors (Table 14.2). The primary factors that influence the difficulty of third molar surgery (length of procedure and related complications) will depend on patient factors, the depth of application, and proximity to vital structures.³⁸

A study of 4004 patients showed a 1.5 times likelihood of a complication if the patient had third molars removed at over 25 years of age, with generalized increasing risks with age through to age 65.⁴⁸ A consensus of the literature supports the concept that postoperative risks from third molar removal increase with age.²⁸

Table 14.2 Risk factors.

Factors	Complication risk	Reference
Patient factors		
Age <25 years	Reduced	Mercier 1991 ³⁹
Age >25 years	Increased	Bruce 1980 ⁴⁰ Phillips 2003 ⁴¹ Valmaseda-Castellón <i>et al.</i> 2000 ⁴² Gbotolorum <i>et al.</i> 2007 ²⁸
Ethnicity	Non-Caucasian – longer operating time	Renton <i>et al.</i> 2001 ³⁸

Grade of difficulty

1. Pell and Gregory classification.⁴⁹ Describes the relationship of tooth to anterior border of ramus (1, 2, 3) and relationship of tooth to occlusal plane (A, B, C) (Table 14.3). The level of impaction was determined using Pell and Gregory classification. In another study Pell–Gregory classification has been found to be an unreliable predictor of difficulty in extracting impacted lower third molars.⁵⁰
2. Winters lines⁵¹ (Fig. 14.18).
3. Pederson method of assessment of difficulty (Table 14.4).
4. Yuasa classification of difficulty²⁴ (Table 14.5).
5. Renton *et al.* 2001.³⁸ The main factors that prolonged operative time for third molar surgery in 1400 patients were in order of importance:

- depth of impaction;
- density of bone;
- age of patient/ethnicity of patient;
- proximity to IAN canal;
- surgeon.

There are many types of grading methods for the assessment of difficulty of third molars. The author believes that the most important factors are:

- patient factors (cooperation, age, ethnicity, and mouth opening);
- dental factors (application depth, root morphology, and condition of teeth);
- surgical factors (surgeon technique and training).

The suggested methods for difficulty assessment may assist the less experienced surgeon.

Fig. 14.18 Winter's lines. The most important factors may be remembered by using the mnemonic WHARFE: W, angulation using Winter's lines; H, height of mandible; A, angle of second molar; R, root form and development; F, size of follicular sac; E, exit path of tooth to be extracted.

Table 14.3 Pell and Gregory classification.

(1) Position A	The highest portion of the impacted mandibular third molar is on a level with or above the occlusal plane
(2) Position B	The highest portion of the impacted mandibular third molar is below the occlusal plane but above the cervical line of the second mandibular molar
(3) Position C	The highest portion of the impacted mandibular third molar is below the cervical line of the second mandibular molar
(4) Position I	None of the crown is in the ramus of the mandible
(5) Position II	Less than half of the crown is in the ramus
(6) Position III	More than half of the crown is in the ramus

Table 14.4 Difficulty index for removal of impacted mandibular third molars, as described by Pederson.⁵²

Classification	Value
Spatial relationship	
Mesoangular	1
Horizontal/transverse	2
Vertical	3
Distoangular	4
Depth	
Level A: high occlusal level	1
Level B: medium occlusal level	2
Level C: deep occlusal level	3
Ramus relationship/space available	
Class 1: sufficient space	1
Class 2: reduced space	2
Class 3: no space	3
Difficulty index	
Very difficult	7–10
Moderately difficult	5–6
Slightly difficult	3–4

Table 14.5 Yuasa’s classification of difficulty of surgical removal of impacted third molars. The key factors indicating highest degree of difficulty are listed.

Depth or ramus relationship/space available or width of root on rotational panoramic images predicts difficulty	
Depth is deep occlusal level	Level C
Ramus relationship/space available is no space	Class 3
Width	Bulbous

Note: abnormal root curvature is not seen in some radiographs.

Presurgical management

Once it has been decided that a third molar should be removed, consideration should be given to the appropriate treatment setting. Patient factors, both local (spreading infection) and systemic (bleeding tendency), will dictate possible treatment strategies. Pretreatment may be necessary for persistent local infection or a medical condition. Essentially the practitioner must assess the patient's demeanor. If the patient is unable to cooperate with routine dental care, or too anxious for care under local analgesia, patient management will need to be modified accordingly.

Referral

Many general dental practitioners will feel suitably competent to manage routine or even complicated third molars, although this does not preclude direct referral to a department of oral surgery or a specialist practitioner. The basis of this decision should take account of the general suitability of the facilities and training for operative procedures, the recovery facilities, and the competence of support staff. In addition, each case should be assessed with regard to the patient's medical history, patient preferences, and the expected degree of difficulty of surgical treatment.

The referring clinician should provide information as to the clinical findings on presentation, medical history, and any radiographs pertinent to the case. Ideally all preoperative radiographs should be shared between clinicians concerned with the assessment and treatment of the patient. The operating surgeon should retain a duplicate in situations where the level of morbidity raises concern.

A discharge letter should always be sent to the referring clinician outlining the treatment plan, specific information provided to the patient, the form of anesthesia, and what follow-up arrangements are required.

Consent

Obtaining informed consent is a general legal and ethical principle that must be undertaken before surgical intervention. Valid consent must be obtained before starting treatment or physical investigation, or providing personal care, for a patient. This principle reflects the right of patients to determine what happens to their own bodies, and is a fundamental part of good practice.⁵³ Patients have a right to choose whether or not to accept a dental professional's advice or treatment.

In the UK the General Dental Council (GDC) has set standards for dental professionals⁵³ and recommends the following principles in getting consent:

1. Informed consent – the patient has enough information to make a decision.

Table 14.6 Types of NHS consent forms.

Consent form 1	Patient agreement to investigation or treatment
Consent form 2 Under 16 years of age	Parental agreement to investigation or treatment for a child or young person under 16 years. If a child is under 16 years but deemed to be competent they can consent to their treatment
Consent form 3	Patient/parental agreement to investigation or treatment (procedures where consciousness not impaired)
Consent form 4	Form for adults who are unable to consent to investigation or treatment

2. Voluntary decision-making – the patient has made the decision.
3. Ability – the patient has the ability to make an informed decision.

The Department of Health (2009)⁵⁴ in the UK has recently introduced four consent forms for NHS patient interventions (Table 14.6).

Patient information

It is recognized that good communication is central to the clinician–patient relationship and to good clinical care. Patients require information about the options available for management of their third molars, together with an explanation of the operation/procedure itself.

At the preoperative appointment, the potential outcome of any chosen course of action, adverse or otherwise, should be explained to the patient in terms that they can easily understand. Details should be noted in the patient's records and should include aspects relating to the patient's quality of life. In addition, care should be taken to explain to the patient the consequences of not having the tooth removed and other treatment options which may be required in this event.

The information provided should be sufficient to enable the patient or their carer to make a valid informed decision and give consent (a minimum of 24 hours prior to surgery).⁵⁵ The US National Institutes of Health recommend that patients should be informed of potential surgical risks including any transitory condition that occurs with an incidence >5% and any permanent condition with an incidence >0.5%.^{4,5} If the patient is at increased risk of inferior alveolar nerve injury based on radiographic assessment then the patient must be warned of the increased odds.^{26,55,56}

At the time of surgery, the patient should be reminded of the possible complications and side-effects of the operation. The operator should ensure that consent has been obtained, that the patient still wants to go ahead with the procedure, and a note should be made in the patient's records.

At the time of the operation the patient should know:

- How to contact the surgeon in case of emergency.
- How to look after their mouth postoperatively (sutures, etc.).
- Possible complications and side-effects of the operation in general and any problems specific to the operation undertaken.
- Any drug therapy required.
- Whether a review appointment is required and if so, when.
- That postoperatively the referring practitioner will receive a letter detailing the treatment undertaken.

The medically compromised patient

There are some medical conditions which have to be taken into consideration. Medically compromised patients are covered in more detail in Chapter 3. Table 14.7 presents some medical conditions which are especially important to consider for third molar surgery.

Every effort should be made at the time of the operation to minimize or avoid complications and side-effects of the operative procedures.

Medications commonly used in oral surgery

Anxiety and pain relief

General anesthesia

Methods of anxiety and pain relief include local analgesics, local analgesia with intravenous sedation, and general anesthesia. It is common practice to use local analgesia. Appropriate selection of patients for local analgesia versus local analgesia plus sedation, or outpatient or inpatient general anaesthetic is often confusing for those new to the specialty. In essence surgery taking longer than 40 minutes should be limited to patients with sedation-augmented procedures or outpatient general anesthesia. Medical conditions may restrict the provision of day case anesthesia and lead to the necessity of general anesthesia (Fig. 14.19). In general dental practice, the former two methods are considered appropriate, but still require suitable facilities to be available.⁶⁵ General anesthesia may be needed for complex and lengthy procedures but it must be recognized that local anesthesia carries less risk.⁶⁵ Recent General Dental Council guidance emphasizes that general anesthesia is a procedure which is never without risk and that *"in assessing the needs of an individual patient, due regard should be given to all aspects of behavioural management and anxiety control before deciding to prescribe or to proceed with treatment under general anaesthesia"*.⁶⁶

Fig. 14.19 Local analgesia/anesthesia/sedation flow chart.

Sedation

One must be aware of differences between sedation practice in the UK and the US. UK conscious sedation is limited to single drug use, commonly midazolam, and maintenance of verbal communication with the patient.⁶⁷ US sedation is nearer a UK-defined general anesthetic with use of multiple drugs (commonly propofol and midazolam) and laryngeal mask airway. Day cases by definition in the UK are cases admitted and discharged within a day (12 hours), however day cases in the US are allowed to stay for one night and are generally discharged within 24 hours. Most oral surgeons in the US undergo anesthesia training for provision of non-conscious sedation in their surgeries. Conversely all general anesthetics and multiple drug sedations are undertaken in the hospital setting in the UK.

Local analgesia

There have been several recent reports of successful routine removal of upper third molars with placebo palatal local anesthesia (21 patients, split-site design using buccal lidocaine)⁶⁸ and without palatal analgesia (root canal treatment, 53 patients using buccal articaine).⁶⁹ The author routinely elevates maxillary third molars with buccal lidocaine infiltration as the discomfort of the palatal injection appears to be significantly greater than that perceived during extraction.

Many practitioners already undertake routine dental and third molar extractions with articaine-only infiltrations. Currently there is no evidence base for this practice, however in the author's department a prospective randomised study is underway evaluating the scope of articaine infiltration only for mandibular dentistry.

Table 14.7 Common medical problems influencing management of dental patients.

Medical condition	Recommendations	Reference
Infective endocarditis (IE)	Antibiotic (AB) cover for dental treatment not recommended Patients at risk of IE should maintain high standard of oral health Chlorhexidine mouthwash is not recommended Dentists must warn patients about IE symptoms	NICE draft 2007 ⁵⁷ American Heart Society (1997) ⁵⁸
Steroid	No evidence base for steroid cover Patients should take their normal dose Cover is required for surgery under GA or if patient has missed their routine steroid dose unless patients receiving <10 mg of prednisolone or equivalent in which case they do not need steroid cover Steroid cover may be required if steroid cover has been taken within 3 months Moderate surgery – preoperatively 25 mg of IV hydrocortisone followed by 25 mg IV every 8 hours for 24 hours. Usual preoperative dose then continued Major surgery – usual dose of steroids preoperatively, then a 50 mg of IV hydrocortisone followed by 50 mg IV 8 hourly for 48–72 hours. Continue this infusion until the patient has started light eating, then restart normal preoperative dose	EMIS 2007 ⁵⁹
Warfarin Coumadin	Check on day of surgery or 3 days beforehand No adjustment of warfarin is required unless international normalized ratio (INR) >4 for routine extractions Multiple or difficult surgical extractions may require heparin management undertaken by hematologist	North West Medicines Information Centre 2007 ⁶⁰ FDA 2009 ⁶¹
Tranexamic acid	Mouthwash is not recommended	North West Medicines Information Centre 2007 ⁶⁰
Bisphosphonates	Prior to treatment with an IV bisphosphonate a dental examination with appropriate preventative dentistry should be considered The surgeon must complete all necessary invasive procedures prior to IV bisphosphonates. Prophylactic extractions should be undertaken with a view to short arch strategy in order to prevent necessary future extractions and surgery. Regular dental check-ups should be arranged, with necessary oral hygiene, chlorhexidine mouthwashes, and topical fluoride treatments After/during treatment avoid extractions/surgery On development of osteonecrosis of the jaw while taking a bisphosphonate, dental surgery may exacerbate the condition If an invasive dental procedure cannot be avoided there are no data to suggest whether discontinuing bisphosphonate treatment reduces the risk of osteonecrosis of the jaw	Marx <i>et al.</i> 2007 ⁶² Mehrotra & Ruggiero 2006 ⁶³
Previous radiotherapy involving the jaws	Similar recommendations to IV bisphosphonates No evidence that antibiotics improve outcome Pentoxifyline 400 mg q12h, vitamin E 1000 IU, chlorhexidine 10 ml q6h Hyperbaric oxygen may have an effect? No evidence base Ultrasound therapy no evidence Short arch (leave 5–5 and remove molar teeth) prior to radiotherapy Oral fluoride supplements before, during radiotherapy and afterwards	Katsura <i>et al.</i> 2008 ⁶⁴
Patient with human immunodeficiency virus (HIV)	Viral load HIV RNA 50 k/ml high infectivity CD4 count: >200 cells/ml Rx as normal <200 cells/ml check blood profile Check for neutropenia, thrombocytopenia, liver function, coagulation screen	

There is continued debate about high concentration local anesthesia being related to increased incidence of inferior alveolar and lingual nerve injuries during block injections but there is a limited evidence base. The nerve injury may be related to concentration of articaine rather than the agent itself. The use of 5% lidocaine was abandoned many years ago due to its neurotoxicity. The AAOMS white paper⁵ states that there was no difference in nerve injuries with articaine in a longitudinal study in the US but there was an increased incidence with prilocaine.⁵ Some reports state that 4% articaine is no more effective than 2% lidocaine⁷⁰ and routine 2% lidocaine IAN blocks are generally recommended. Increasingly practitioners are undertaking articaine buccal infiltration-only extractions in adults and children and the author believes this will soon become standard care with use of top-up lidocaine 2% IAN blocks when necessary.

Antibiotics

The use of prophylactic antibiotic therapy following third molar surgery is a common, if not universal, practice. There is very little evidence to support its routine use and there is, however, a growing body of data to suggest that this practice wastes resources with very little prospect of health gain. The use of broad-spectrum, third-generation antibiotics seems completely unacceptable;^{71–73} however, in severe cases, where there is acute infection at the time of operation, significant bone removal, or prolonged operation, antibiotics should not be withheld. The bacteriology of the wisdom tooth socket and the research that was related to it was beautifully described by MacGregor.⁷⁴ He concluded, “*Antimicrobial drugs appear to have a marginal benefit in third molar surgery when clinically uninfected teeth are removed.*” Over 30 years later, little appears to have changed.

Analgesia

Third molar surgery is the gold standard used for the evaluation of analgesics for the management of moderate to severe acute postsurgical pain.⁷⁵ Peak pain levels occur after the local analgesia has worn off at 4–6 hours and lasts for up to 12 hours.^{76,77} Normal practice is to prescribe or advise oral analgesics such as paracetamol or ibuprofen for outpatients.⁷⁶ For inpatients a number of options including non-steroidal anti-inflammatory agents and opiates are commonly prescribed. Pre-emptive analgesia may be considered, however evidence base does not support this practice.⁷⁸ The most effective analgesia is diclofenac (number needed to treat (nnt) 2.3) followed by Ibuprofen 400 (nnt 2.6) 600mg every 6 hours.⁷⁸ Many authors routinely recommend combined non-steroidal anti-inflammatory agents (if not contraindicated) with paracetamol as the best combination for acute postsurgical pain,

avoiding complications associated with opiate and opioids.⁷⁸

Steroids

Where there is a risk of significant postoperative swelling, pre- or perioperative administration of dexamethasone or methylprednisolone has been shown to reduce swelling and discomfort.^{78–80} For nerve injury, the window of opportunity for treatment with high-dose prednisolone is within the first 72 hours (some even say the first 48 hours). The protocol based on treatment for facial palsy may have a role in minimizing inflammatory injury to peripheral nerves. This involves a step-down prednisolone treatment of 20mg for 5 days, 10mg for 5 days then 5mg for 5 days.

Chlorhexidine

There is sufficient evidence base for the routine prescription of chlorhexidine prior to or after third molar surgery in order to reduce alveolar osteitis (dry socket).⁸¹

Surgical procedure

The procedure is variable and is influenced by patient factors, including the type of impaction and anatomy of surrounding structures, for example proximity of the inferior alveolar and lingual nerves. Generally surgery involves the raising and protection of soft tissue flaps and bone removal with either chisel or bur with water cooling irrigation. There is conflicting evidence as to the most appropriate form of protection for the lingual nerve.^{82,83} However the evidence base highlights that temporary lingual nerve injury is reduced when lingual access is avoided.^{42,46}

The whole tooth should be removed and wound toilet completed. Any suspected pathological material should be sent for a histopathology report.

Principles of exodontia of third molars without using a flap

Suitable instrumentation for surgical extractions of third molars is shown in Fig. 14.20. The surgeon should scrub in using sterile gloves, mask, and head cover and draping of the patient should be carried out (Fig. 14.21). A mouth prop on the contralateral side allows the patient to relax with an open mouth (Fig. 14.22). It is important to support the patient's head and mandible (Fig. 14.23).

Simple forceps extraction of erupted third molar is similar to any other extraction using forceps and is covered in Chapter 12. Elevation of a mandibular molar is possible when the tooth is erupted and vertically impacted. If the tooth is minimally meso- or

Fig. 14.20 Suggested instrumentation for routine dentoalveolar surgery.

Fig. 14.24 Elevation of mandibular vertical, non-impacted, lower left third molar. (a) Preoperative radiograph. (b) Clinical view of non-impacted 38. (c) Placement of straight Warwick James elevator either at the mesial or buccal aspect of the lower left 8 in order to elevate. (d) (i) Ideal path of elevation of a single rooted erupted lower 8; (ii) when placing the elevator at the mesial aspect, avoid pressure on the distal aspect of the adjacent second molar. This may result in fracturing of the crown of the second molar, particularly if it is heavily restored or non-vital.

disto-angularly impacted, elevation may be possible, particularly in younger patients and with favorable root morphology (Fig. 14.24).

If the tooth is partially erupted, a relieving incision and elevation (Warwick James method) is carried out (Fig. 14.25). This is a very useful method that allows the surgeon to place a small (less than 3 mm) incision through the disto-buccal aspect of the gingival cuff overlying the partially erupted tooth.

After the cuff is relieved (similar to an episiotomy) a Wards periosteal elevator can be used to establish if any bone is overlying the distal aspect of the crown of the tooth. If there is no overlying bone, the vertical or mesoangular tooth can be elevated with a straight Warwick James elevator as the mucosal impaction has been relieved; often no further mesial relieving mucosal incision or bone removal is necessary.

Fig. 14.25 (a) Partially erupted 38 before incision. (b) Relieving incision and elevation for partially erupted third molar. Incision using #15 blade. Essentially the blade is placed buccally at the distal aspect of the gingival cuff and the incision extended to the periodontium of the 38 (length of incision is usually 4–5 mm). (c) Right-curved Warwick James is placed at the mesial aspect of the lower left 8 and the tooth is elevated superiorly and buccally. Once the tooth is mobilized and superiorly displaced the same Warwick James can be placed in the furcation of the lower left 8 and the tooth elevated.

Surgical extraction of third molars

Flap design

A single “slash” is commonly used to access unerupted maxillary third molars (Fig. 14.26). Maxillary third molars rarely require sectioning because the overlying bone is thin and relatively elastic. Usually extrac-

tion is accomplished by removing additional bone rather than by sectioning. For maxillary third molars, bone removal is done primarily on the lateral aspect of the tooth down to the cervical line to expose the crown. Frequently, the bone is thin enough that it can be removed with a periosteal elevator or a chisel with hand pressure.

Fig. 14.26 Flap design for removal of maxillary third molar. (a) Preoperative view of 18. (b) Local anesthesia – buccal infiltration. (c) Placement of Minnesota retractor and incision with #15 blade. (d) Elevation of buccal flap, 18 retracted with Minnesota retractor. (e) Elevation upper root 18 with right-curved Warwick James elevator. The tooth is delivered with curved elevators applied on the mesio-buccal with rotational and lever types of motions. The tooth is always delivered in a disto-buccal and occlusal direction. (f) Socket 48 after extraction. Irrigate socket and use gloved finger to ensure no bony spicules are present and that the buccal plate is not fractured. No suture is necessary as the buccal flap remains sealed by the pressure of the cheek.

Mandible envelope flap

See Fig. 14.27a. A disadvantage is that the long distal incision to allow reflection of the flap is more likely to expose distal bone of the 8 and thus tempt the surgeon to drill distal bone and place the lingual nerve more at risk.

Mandibular buccal triangular flap

See Fig. 14.27b. The advantage of this minimal access flap is that there is sufficient exposure for buccal bone removal and tooth section without extensive periosteal stripping of the buccal aspect of the mandible or temporalis muscle attachment, resulting in significantly less postsurgical pain and swelling. The triangular flap is best used with a Minnesota retractor providing buccal and flap retraction in one.

Mandibular bone removal

See Fig. 14.27c. An air-driven or electric hand piece with round or fissure burs is used. If using the preferred buccal approach to minimize lingual nerve injury, a fissure bur should be used to get clean sec-

tions for tooth splitting for elevation. For mandibular teeth, bone on the occlusal and buccal (**NOT distal**) aspects of the impacted tooth is removed beyond the cervical line down to the roots of the tooth. It is advisable not to remove bone on the lingual aspect due to the likelihood of damage to the lingual nerve.

Sectioning the tooth

See Fig. 14.27d. Using a fissure bur allows the surgeon to get a narrow clean section into the dental pulp then extend the “incision” within the confines of the tooth. At no point should the bur breach the mesial, distal or lingual surfaces of the tooth. Thus one achieves a “partial” section of the tooth covering about 40% of the split surface.

Planning tooth section

Planning potential tooth sectioning is important and saves operative time (Fig. 14.27e). Depending on the depth of application point and the angulation, the crown or root will need to be sectioned. When sectioning the roots the surgeon can use the dental pulp

Fig. 14.27 (a) Mandibular envelope flap, not recommended due to the long distal extension required. (b) Triangular flap. (c) Bone removal is performed using a fissure bur at full speed adjacent to the enamel of the crown. The gutter or trough should be kept narrow (bur's width) and extend **inferiorly only** to the furcation of the tooth to allow elevation of the roots later without further bone removal. The bone cut should *not* extend beyond the mesial aspect of the crown *or* the buccal aspect of the tooth distally (see diagram). (d) Surgical approach to sectioning of the tooth for vertical, mesial, horizontal, and distoangular angulation. (i) Sectioning options for mandibular mesoangular third molar impactions. This view shows a cut longitudinally through the furcation. (ii) Same as (i), but with an additional cutting of the mesial crown, which is wedged under the second molar. (iii) Crown and root separation. The crown is removed and then the root is delivered into the original crown space. (iv) Crown removal as in (iii), but then the roots are divided longitudinally through the furcation and moved into the crown space for removal. Mesoangular – no section, i, ii, iii, iv; vertical – none, i; distoangular – none, iii, iv; horizontal – none, ii, iii, iv. (e) Using a fissure bur as near to the crown root junction of the 8 and as near to 90 degrees to the tooth (i). The tooth should be perforated until one feels the pulp chamber (ii). Then the cut should be lateralized or verticalized depending on whether you intend to decoronate the tooth or vertically section it. Using a straight Warwick James elevator the crown should be "factured off" (iii). If the roots require sectioning the fissure bur cut should *not* extend outside tooth material (iv) and the ideal underside of the sectioned crown should be cut only from the buccal aspect covering about 40% of the split surface (v). From the buccal aspect the crown section cut should be confined to the buccal surface and *not* extend through distal, mesial or lingual surfaces of the tooth.

chambers to estimate where to split the roots. Again at no point should the drill cut extend through the lingual aspect of the roots. Often drilling a small hole large enough to engage the tip of a curved Warwick

James elevator is useful in gaining a “purchase point” to elevate the roots. Figs 14.28–14.31 illustrate surgical extraction of third molars.

Fig. 14.28 Buccal flap with buccal bone removal for partially erupted third molar with deeper depth of impaction. (a) Preoperative film, 38 erupted non-impacted. (b) Clinical picture, 38 erupted, non-impacted. (c) Buccal bone removal with fissure bur to achieve narrow gutter. (d, e) Tooth elevated with contralateral (right) Warwick James elevator at mesial application point. This elevates the conical rooted tooth in a vertical and buccal direction. As the tooth moves superiorly the same Warwick James can be placed in the now exposed furcation of the tooth and final delivery is controlled. (f) After irrigation of the socket the buccal triangular flap is secured with a single 4/0 Vicryl Rapide suture.

Fig. 14.29 Surgical removal of mesoangular tooth with buccal bone removal and vertical section. (a) Preoperative radiograph. (b) Clinical picture of partially erupted lower left 8. (c) Triangular buccal flap raised and retracted with Minnesota retractor. (d) Removal of buccal bone with fissure bur to form a gutter. (e) Vertical section of tooth using a fissure bur. (f) Using a straight Warwick James to "crack" the tooth into vertical sections. (g) Tooth cracked vertically. (h) The distal section of tooth elevated with No 1 Couplands. (i) The distal segment is elevated. (j) Using a contralateral Warwick James elevator mesially the mesial segment of tooth is elevated. (k) Irrigation of socket with saline. (l) Reapproximation of tooth out of the mouth to demonstrate that the tooth cut only penetrates into the dental pulp (m) not through the whole tooth in order not to penetrate the lingual aspect of the tooth.

Fig. 14.30 Extraction of a distoangular 38. (a) Preoperative radiograph. (b) Clinical appearance. (c) Buccal bone removal. (d) Section of crown. (e) Elevation of crown. (f) Elevation of the crown, then elevation of the roots with curved Warwick James elevator. (g) (i) Use Warwick James elevator to elevate roots together. If roots are immobile, section with fissure bur (ii) then elevate roots separately (iii).

Fig. 14.31 Surgical removal of a horizontal 48. (a) Preoperative radiograph. (b) Preoperative clinical picture. (c) Flap raised using Wards periosteal elevator. (d) Removal of buccal bone with fissure bur to form a gutter. (e) Splitting of vertically sectioned tooth using Warwick James straight elevator. (*cont'd*)

Fig. 14.31 (cont'd) (f) Elevation of distal root using No. 1 Couplands. (g) Elevation of mesial root using curved left Warwick James elevator. (h) Approximation of wound prior to suture. (i) Alternative sectioning of a horizontal tooth may require decoronation (notice the angulation of the crown–root junction cut with narrowing of section inferiorly to maximize the ability to elevate the crown in one piece (i). If the crown is too impacted then section the crown into two pieces and then elevate the crown. This leaves the roots *in situ* (ii). Using the pulp chambers as “guide” one can section the roots with a fissure bur and then elevate the roots individually. The order will depend on root curvature. Drilling a small notch into the root surface will often facilitate root elevation (iii).

Lingual flap elevation and lingual retraction

Most third molars can be removed by using a purely buccal technique preventing the necessity to encroach on the lingual tissues or to remove distal, disto-lingual or lingual bone.^{84,85} However, on occasion where the tooth is malpositioned, or for other reasons, it may be necessary to remove distal, disto-lingual, or lingual bone. If this is necessary, a subperiosteal lingual flap is raised with a suitably curved periosteal elevator that can stay in contact with the lingual plate of bone and not encroach on the lingual soft tissues.^{86,87} Once a subperiosteal lingual flap has been raised, a lingual retractor is placed. The evidence base suggests a significantly higher incidence of temporary lingual nerve involvement when a lingual retractor was used.⁴⁶ Thus this author does not advocate the routine use of lingual access for third molar surgery unless there are roots perforating the lingual plate that require removal, or the position of the tooth and associated pathology dictate its necessity.

Alternative procedures

Coronectomy

Coronectomy (also known as partial tooth removal, partial odontectomy or intentional root retention) (Figs 14.32 and 14.33) has been reported in five articles reporting series of patients. Four were case series,^{88–91} the fifth article was a randomized controlled trial.²⁶ In all cases, coronectomy was suggested as a technique of partial root removal when panoramic radiographic imaging suggested an intimate relationship between the roots of the lower third molar and the IAN and the vital tooth still needed to be removed. (Note: CBCT was not available at the time the studies were conducted.) Antibiotics are rarely recommended. Two papers mentioned that the socket should be closed primarily. Two papers stated that lingual retraction was recommended in all cases to protect the lingual nerve.^{88,89} Two papers did not use lingual retraction.^{90,91} This recommendation may reflect the different techniques applied in the studies; when complete section of the crown from the roots is undertaken then lingual protection would be advised,⁸⁹ however Renton *et al.*²⁶ recommend partial section of the crown as in the buccal technique described in this chapter which requires no lingual protection. Inadvertent root mobilization at the time of attempted coronectomy occurs in 3–38% of patients, thus failing to achieve coronectomy and the roots needing to be removed at the time of primary surgery.^{88–91} One paper noted a 38% failure rate at primary surgery, because the roots were only sectioned about halfway into the pulp chamber, before an attempt was made to split the roots from the crown.²⁶ Mobilization of the roots occurred in many cases and did result in an 8% incidence of temporary IAN involvement but no

permanent injuries. Factors that increased the likelihood of root mobilization were female patients, conical roots, and age <30 years.²⁶ Later root removal may be required in 2–6% of cases depending on the technique of coronectomy employed.^{88,89} Subsequent root migration is mentioned in all papers: 14–81% showed later migration of the roots towards the superior border of the mandible. Roots may require removal when they erupt later and become infected but often the roots have migrated away from the IAN thus minimizing potential injury to the nerve. Prevention of permanent IAN injury occurred with coronectomy technique with one exception: O’Riordan⁸⁸ reported this due to inadvertent drilling, in 1% of patients in one study.

It is generally recommended that when imaging suggested an intimate relationship between the roots of the lower **vital** third molar and the IAN and the tooth still needs to be removed, consideration should be given to coronectomy with retention of the portion of the roots associated with the IAN. This procedure may be contraindicated in patients who are immunocompromised or have had previous radiotherapy in the region.

Eruption of third molar

Many studies have been done to attempt to predict the probability of third molar eruption, most of them using dissected skulls or lateral cephalic radiographs. The lateral cephalic radiograph is an excellent aid in performing cephalometric diagnoses. Using dental pantomograms, Quirós and Palma presented a method for prediction of third molar eruption and optimal timing for extractions of third molar into second molar space. It is not possible to predict eruption of third molars in all cases; adequate space between the anterior border of the mandible and the distal of the mandibular second molar seems to be necessary to allow successful eruption to the occlusal plane. The AAOMS⁵ white paper highlights several issues:

1. The most significant variable associated with third molar impaction is inadequate hard tissue space, with the vast majority of impacted third molars having space/crown width ratios of less than 1.^{92,93}
2. It is possible to measure space for eruption to the occlusal plane using a variety of radiographic techniques.^{92,94}
3. Third molars that remain impacted after the age of 25 may still change in position.⁹⁴

Orthodontic traction

A recent suggestion is to orthodontically “extract” third molars in those patients at risk of bisphosphonate-induced osteonecrosis. This method may assist in preventing this unfortunate complication.⁹⁵

Fig. 14.32 Coronectomy. (a) Radiograph of vital vertically positioned lower right 8 with roots crossing IAN canal. (b) Buccal bone removal with fissure bur. (c) Sectioning of crown from roots level with the crown root junction subsequent to buccal bone removal with fissure bur. (*cont'd*)

Fig. 14.32 (cont'd) (d) Elevation of crown from roots with straight Warwick James. Usually the crown will elevate whole but if it is still impacted (too wide for space) then, using a fissure bur, the crown can be vertically sectioned to allow elevation of the crown. (e) Cracking crown apart into two segments using straight Warwick James. (f) Crown fragments extraorally. (g) Coronectomized roots *in situ*. The pulp chamber and live pulp can be seen. No dressing is necessary but you must ensure no enamel is left behind and trimming with a rose head bur may be necessary. (cont'd)

Fig. 14.32 (cont'd) (h) Closure of "socket" with single 4/0 Vicryl suture. (i) (i) Preoperative radiograph of high-risk third molar. (ii) Postoperative radiograph of coronectomized third molar. (j) (i) Preoperative radiograph of high-risk third molar and second molar with dentigerous cyst. (ii) Postoperative (6 weeks) radiograph of coronectomized third molar and second molar with enucleation with good clinical healing.

Fig. 14.33 Series illustrating failed coronectomy resulting in decision for the removal of the mobilized roots during surgery. (a) Radiograph illustrating vital lower left 8 in close proximity to the IAN canal. (b) Elevation of crown after section with fissure bur. During the crown elevation the roots mobilize, thus root removal is indicated. (c) (i and ii) Use of contralateral Warwick James elevator to elevate tooth. (d) Continued elevation of lower left 8 with "Warwick James method".

Autotransplant

Transplantation of immature third molars is a safe, useful procedure when appropriate conditions of the recipient site are present. Where the alveolus is atrophic, a splitting osteotomy should be performed only in exceptional cases and preference should be given to alternative methods such as primary bone augmentation or bone-regenerative procedures.⁹⁶

Germectomy or lateral trepanation

For the purposes of this chapter germectomy is defined as the removal of a tooth that has one third or less of root formation and also has a radiographically discernible periodontal ligament. It does appear that early third molar removal (6–17 years) may be associated with a lower incidence of morbidity and also less economic hardship from time off work for the patient. However, this is not recommended practice.^{97,98}

Restoration of adjacent tooth

Due to the routine practice of prophylactic surgery deep distocervical carious lesions of the adjacent 7s are rarely seen in the US and have become a UK phenomenon. This condition is increasingly seen in the UK where prophylactic surgery is avoided and as a result patients may present with distocervical caries of the second molar. These lesions are relatively inaccessible for the general practitioner and best access may be available during third molar surgery. There is limited evidence base for restoration of deep distocervical caries of the second molar on removal of the adjacent third molar. Excavation of caries with placement of glass ionomer cement is possible and may become routine practice in maximizing the prognosis of the second molar tooth in these cases.

Obliteration of third molar tooth bud

A recent report illustrates that in dogs the use of an intraoral 100Watt diode laser can prevent the development of third molar teeth. In the future this may have a role in selectively stopping third molar surgery.⁹⁹

Periodontal therapy

The periodontium distal to the mandibular second molar may be affected by removal of an impacted third molar.^{100,101} Some authors suggest specific strategies to minimize periodontal pocketing subsequent to third molar extraction including: scaling, root planing, and plaque control,¹⁰⁰ guided tissue regeneration,¹⁰² and platelet-rich plasma.¹⁰³

Other techniques

Fig. 14.34 shows pictures of retained root retrieval using a Mitchell trimmer to engage the (previously drilled) hole in the side of the tooth segment and elevate the root segment. Fig. 14.35 demonstrates enucleation of a cyst in association with a third molar.

Outcomes of third molar surgery

Outcomes in response to surgical or non-surgical management of third molar teeth may be successful or unsuccessful. Outcomes must be defined and quantified to enable audit to establish best practice. The success or otherwise of the procedure ideally should be viewed from the perspective of the patient.

A review appointment may be required.¹⁰⁴

- when non-resorbable sutures have been placed;
- when complications arise;
- at the patient's or surgeon's request.

Successful outcome

This is achieved when the presenting symptoms and signs of disease associated with a third molar tooth have been eliminated and the tissues have fully healed with no residual functional deficit. During normal healing it is usual for the patient to experience some discomfort, swelling and trismus over the first 3 postoperative days. Symptoms should gradually resolve over the next 2 weeks.

- Pain visual analog scale (VAS). The inflammation induced by surgical trauma results in pain of which the patient must be forewarned. This will be worst in the first 24 hours postoperatively and should be resolved within 3–4 days. If pain persists there may be dry socket or infective complications.
- Hemorrhage must be controlled at the time of surgery. Soft tissue bleeding may require hemostatic agents, bipolar diathermy, and/or sutures. Occasionally a small amount of bone wax is necessary to control bleeding from bone, but this must be used with caution. Hematoma formation outside the socket can occur and may require drainage.
- Ecchymosis. Patients should be informed that bruising is common and self-limiting and will usually resolve within 2 weeks of surgery.
- Swelling caused by surgically induced inflammation is a common sequel and usually correlates with the degree of difficulty of surgery. The patient must be warned of this risk and advised that it should resolve within 24–36 hours.

Fig. 14.34 Root retrieval using a bur hole into the root (a) will facilitate leverage. Standard technique using curved Warwick James or Cryer elevators (b) to remove interradicular bone and elevated retained root (c, d). Root tips can often be elevated using a Mitchell's trimmer.

Fig. 14.35 Enucleation of cyst in association with 38. (a) Radiograph of unicystic lesion associated with 38. (b) Cavity after enucleation of cyst. (c) 38 with associated dentigerous cyst lining.

- Trismus. Limited interincisal opening is related to the inflammation around the masseter insertion. This is interlinked with postoperative pain and swelling and should also resolve at 3–4 days postsurgically.⁵⁶
- Sensitivity. Subsequent to raising a flap adjacent to the second molar, exposure of root dentine may occur during healing of the third molar socket. This may cause local sensitivity of the second molar during this period.
- Defect. The third molar socket may take several months to completely infill and the resulting defect may cause the patient some concern. It is important to reassure the patient.
- Temporomandibular joint (TMJ) pain may arise due to prolonged opening of the patient's mouth during treatment. The joint may remain painful for several weeks and the patient should be reassured. Minimizing TMJ discomfort may be possible by routinely using a mouth prop for patients undergoing any prolonged dental treatment.

Complications associated with treatment

As noted earlier, removal of third molars is a common surgical procedure and – as with all surgical procedures – there is a risk of operative and postoperative complications. The rate of complications and their severity varies,¹⁴ but the management of common and more serious complications is described below. The following complications carry significant risk of morbidity and may require immediate referral. The patient should be informed, and a record entered in the patient's notes.

- Dry socket. Alveolar osteitis (dry socket) may occur in up to 20% of patients, particularly in those who smoke.¹⁰⁵ Other risk factors include steroid use, contraceptive pill, bone removal with a bur, age, and the "specific bacteria theory" – *Treponema denticola*.¹⁰⁶ The patient must be forewarned of this most common complication after third molar surgery and instructed to return to the surgery if persistent pain arises from the socket at 3–10 days postsurgically. Irrigation with saline (or chlorhexidine 0.2%) and/or placement of an obtundent, such as proprietary iodoform-based medication, usually immediately relieve the pain and the patient seldom returns for repeat treatment. Rarely, osteomyelitis may occur and this must be considered in patients complaining of persistent discomfort or pain. Long-term antibiotic therapy and/or further surgical exploration in a hospital environment are recommended for these patients.
- Retention of root fragment. When a retained root fragment gives rise to symptoms it should be removed. This event may become more common due to the increase in coronectomy procedures.²⁶
- Displacement of tooth or root fragment. A lower third molar or tooth fragment may be displaced into the lingual tissues, particularly if there is a pre-existing lingual plate defect or on occasion a root may perforate the lingual plate. An upper third molar may pass into the infratemporal fossa or the antrum. Appropriate instruments should be in place prior to elevation to help minimize the occurrence of displacement. Where this occurs, every effort should be made at the time of surgery to recover the displaced tooth, but referral to a specialist may be recommended. If a root is displaced into the maxillary antrum, immediate sequential radiographs may assist in identifying whether the root fragment is mobile within the antrum or entrapped under the antral mucosa. This differentiation is important in order to prevent inhalation of the fragment.
- Any tooth or fragment may be at risk of being swallowed or inhaled. In an upright patient the likely route for inhalation is the right main bronchus. The patients particularly at risk are those sedated and having maxillary surgery. All precautions must be taken to protect the airway, particularly in those with depressed cough reflexes (sedated or general anesthesia). The surgeon must be able to see the tooth/fragment at all times. If a tooth is lost, referral to A&E for radiographic assessment of the tooth position (lungs or stomach) is required. Bronchoscopy retrieval is possible for a pulmonary displaced tooth or fragment; however this is a significant surgical complication for the patient and follow-up is essential.
- Infection. Infection of the soft tissues may result in secondary hemorrhage, cellulitis or, rarely, abscess formation.¹⁰⁷ Any active infection should be controlled and any retained roots or bone sequester should be evaluated prior to surgical exploration. Where signs of systemic involvement are present (pyrexia, regional lymphadenopathy) antibiotics should always be prescribed.
- Surgical damage to adjacent structure. Patients should be told about damage to adjacent teeth at the time of surgery or, if under sedation or general anesthetic, when they are fully conscious. The consequences of this damage should be explained to the patient and recorded in the patient's notes. If repair is required, the operator should arrange appropriate management.
- Periodontal healing after third molar surgery. The periodontium distal to the mandibular second molar may be affected by removal of an impacted third molar.^{108,109} Conversely, others have reported no deleterious effects.^{110,112} Early removal of mesioangular horizontal impacted third molars is associated with better periodontal health.¹⁰⁸ The preoperative existence of an intrabony defect, age of the patient (more improvement if patient ≤25 years), and level of plaque control may help to predict adverse outcomes.¹⁰⁸ Flap design does not

appear to negate periodontal attachment loss on the adjacent second molar.¹¹² Guided tissue regeneration (GTR) may be beneficial in instances where there is evidence of significant pre-existing attachment loss. Scaling, root planing, and plaque control have the potential to reduce postoperative loss of attachment.¹⁰⁰

- Fractured mandible/tuberosity. The risk of intra-operative or postoperative fracture following third molar removal may be age related, and one study shows a mean age at fracture to be 45 years.¹¹³ Fractures should be noted at the time of surgery and repaired if necessary. If the operator is unable to do this, he/she must arrange immediate referral to a specialist. Tuberosity fractures may occur and should be treated at the time of surgery. If the operator is unable to do this, he/she must arrange an immediate referral.
- Oral antral fistula. The incidence of oroantral perforation from upper third molar removal may also increase with age past 21 years.¹¹⁴ Oro-antral communication is probably a more frequent occurrence than is realized and thus probably often heals spontaneously. Any such defect identified at the time of surgery (demonstrated with the Valsalva maneuver – blocked nose and forced air through nasal passages results in air leakage through the defect) should be repaired, usually with a buccal advancement flap. Antibiotic therapy, nasal decongestants, and antiseptic mouthwash (antral regime) are advisable and the patient should avoid nose blowing. Review is advisable at 2 weeks in order to ensure that the repair is successful. If the oro-antral fistula is persistent then an antral regime should be initiated for 2 weeks before reparative surgery. The buccal fat pad technique has been shown to be successful.
- Retained foreign body. Any broken instrument should be removed at the time of the operation. If not retrievable, radiographs should be taken if the object is radiopaque, and the patient should be informed and details recorded in the notes. If it is considered that there is a risk of infection a 5-day course of antibiotics should be prescribed. Aspiration should be excluded.
- Nerve damage. The author uses a minimal-access buccal approach for mandibular third molars as lingual flap access surgery is associated with increased temporary lingual nerve injury.¹¹⁵ Complete neural transection of the lingual or inferior alveolar nerves requires immediate nerve repair by an experienced surgeon. Where there is partial damage, gentle debridement and the maintenance of good apposition of the ends is normally undertaken. The patient should be informed of the situation. One recent study has shown that significant improvement in nerve function can be achieved by specialist surgical investigation and repair.¹¹⁶ Late recognition of nerve damage may require further surgical exploration. Persistence of

symptoms beyond 3 months indicates that a return to normal function is unlikely and that consideration should be given to nerve repair.¹¹⁶ Damage to the IAN, leading to persistent hypoesthesia/dysesthesia in its sensory distribution, is less amenable to surgical repair. The prognosis for spontaneous nerve regeneration after 6 months is poor.¹¹⁷

The spontaneous recovery rate for nerve injuries related to third molar removal is quite variable, ranging from 50–100% for both the IAN and lingual nerve.^{118,119} Several papers mention a greater spontaneous recovery rate for the IAN, but this is not well documented.

- Inferior alveolar nerve. The incidence of IAN involvement 1–7 days after surgery is around 1–5%.^{118,119} The incidence of persistent IAN involvement (still present after 6 months) varies from a high of 0.9% to a low of zero.^{25,42,118–120} A mean figure from all studies is around 0.3%.
- Lingual nerve. The incidence of lingual nerve involvement 1 day after surgery (excluding the use of lingual flap elevation) varies from 0.4–1.5%.^{25,119,121} The incidence of persistent involvement (still present at 6 months) varies from 0.5% (with the use of a lingual flap) to a low of 0%.¹²¹ Several studies indicate zero incidence of persistent paresthesia, whether lingual retraction is used or not.^{25,119,122} However, the author believes avoidance of lingual access surgery and appropriate training will avoid lingual nerve injuries.
- Long buccal nerve. Anatomical studies carried out on the long buccal nerve show that it is at risk during the initial incision for many third molar procedures. Branches of it are probably frequently cut during the incision process, but the effects are generally not noted.¹²³ A search of the literature finds no specific reports of long buccal nerve involvement, although one paper did note long buccal nerve involvement when the anatomic position was aberrant, i.e. coming off the IAN once it was already in the canal and coming out through a separate foramen on the buccal side of the mandible.¹²³ Others reported buccal nerve involvement as part of a larger study.¹²⁴
- Mylohyoid nerve. Damage to this nerve has been reported to be as high as 1.5% following lower third molar removal but this is probably due to the use of lingual retraction.¹¹⁸ The use of preoperative or perioperative steroids did not appear to influence the incidence of nerve involvement.¹²⁵

Other potentially chronic complications include:

- Temporal mandibular joint dysfunction.¹²⁶ Avoid operating on patients with TMJ pain as the prolonged opening may precipitate acute TMJ pain.

Appropriate jaw exercises, soft diet, analgesia, and oral appliances may be helpful.

- Psychological complications. Such complications are rare. It is best practice to refer the patient to their general medical practitioner as there may be other underlying contributing factors.¹²⁷

Chapter 15

Surgical Treatment of Impacted Teeth other than Third Molars

Mehran Hossaini

The management of impacted teeth is probably the most common problem in oral surgery worldwide. The strategies and surgical management of impacted third molars are presented in separate chapters in this book. In this chapter general surgical principles for management of other impacted teeth, such as canines and premolars, are covered. Some of them have to be surgically removed. Other impacted teeth can be guided by surgical exposure to erupt spontaneously or by using orthodontic traction. Evaluation, surgical considerations, and techniques are discussed in this chapter. The use of premolars and canines as transplants to another region is covered in a separate chapter in this book.

Introduction

Impacted teeth occur frequently and can be managed in different ways. The various options will be covered in different chapters of this book:

- surgical exposure for guided eruption (will be covered in this chapter);
- surgical removal (general principles for extraction

of impacted canines and premolars are covered in this chapter and the very common impacted third molars and all considerations are covered in Chapters 13 and 14);

- the impacted tooth can also sometimes be used as donor tooth for autotransplantation (see Chapter 17);
- an impacted tooth can also be left in place for observation.

Management of impacted teeth can be challenging. The most important part of this process is to develop an organized approach to establish a diagnosis, formulate treatment options, identify risk, assess benefits, and recognize alternatives.

Definitions

There are various definitions for impacted teeth. The American Dental Association defines an impacted tooth as “an unerupted or partially erupted tooth that is positioned against another tooth, bone, or soft tissue so that complete eruption is unlikely”.¹ The American Association of Oral and Maxillofacial Surgeons’ definition of an impacted tooth is one which is not fully erupted into the oral cavity, usually due to a lack of space, poor positioning or the presence of associated pathology.² It is possible for any tooth to follow an aborted eruptive path and become impacted.² Some have considered the impacted tooth to be pathologic and always requiring treatment. In recent years there has been much discussion and controversy regarding the need for elective treatment of asymptomatic impacted teeth. During the course of this chapter the author will use the definition which does not necessarily consider an impacted tooth to be pathologic.

Incidence

The incidence of impacted teeth varies amongst different sectors of the population. Generally, the most commonly impacted teeth in order of frequency are maxillary third molars, mandibular third molars, maxillary canines, and mandibular premolars.³ Impacted canines are seen in 1–2% of the general population, and occur in females twice as often as in males. Caucasians are affected five times more than Asians. From the anatomic standpoint impacted canines are located palatally in 85% of cases and labially in approximately 15% of cases.⁴

Theories why teeth become impacted

There is much discussion regarding the factors which may contribute to disruption of the normal eruption pattern which in turn leads to impaction of a tooth. Two main theories have been proposed as the possible explanation for the impaction of a tooth. The first is known as guidance theory which identifies the local factors and conditions as the contribution to the impaction of a tooth.⁵ These include conditions such as embryologic displacement of the tooth buds, transposition of teeth, and the presence of supernumerary teeth or odontomas. Other factors affecting the normal path of eruption are congenitally missing teeth, such as lateral incisors; it is believed this disrupts the natural guidance needed to determine the position of the tooth in the dental arch. The second theory is known as the genetic theory, which links impacted teeth to other genetically linked dental abnormalities such as the size, shape, number, and structure of the teeth.⁵ The etiology of impacted teeth has also been linked to systemic conditions, such as endocrine disorders or febrile diseases, syndromes, such as cleidocranial dysplasia,⁶ and local disease processes, such as tumors or cleft lip and palate.⁷

Table 15.1 Sequence of eruption and shedding of primary dentition.

Maxillary teeth	Eruption	Shedding
Central incisor	8–12 months	6–7 years
Lateral incisor	9–13 months	7–8 years
Canine	16–22 months	10–12 years
First molar	13–19 months	9–11 years
Second molar	25–33 months	10–12 years
Mandibular teeth	Eruption	Shedding
Central incisor	6–10 months	6–7 years
Lateral incisor	10–16 months	7–8 years
Canine	17–23 months	9–12 years
First molar	14–18 months	9–11 years
Second molar	23–31 months	10–12 years

Regardless of the etiology, a deviation from the normal sequence of eruption may indicate the existence of disruption of normal tooth eruption. It is prudent for the practitioner to consider and compare the patient's chronological age to the stage of dental growth. The normal sequences of eruption of primary and permanent dentition are demonstrated in Tables 15.1 and 15.2.

Evaluation

Although it is unnecessary to emphasize the importance of patient evaluation, it is prudent to review the different aspects of the evaluation process as it pertains to impacted teeth. The areas that must be covered in the patient evaluation include chief complaint, history of the present illnesses, medical history, clinical examination, and evaluation using appropriate imaging.

One aspect of patient evaluation which remains underemphasized is the patient's chief complaint, expectations, and the history of their present condition. Unfortunately, often patients' chief concerns or complaints are somewhat superficial or even vague. Their dislike of their smile or simple curiosity about their missing tooth may be the only information that is verbalized. A thorough clinician must take the time to explore the simple verbalization of the patients' observations and formulate their primary concerns and expectations; this fact, although basic, is quite difficult to master. Some clinicians are at times unable or unwilling to obtain this information and, worse, may superimpose their own views upon the patients' concerns. It should be recognized that patients' concerns and expectations have great impact upon

Table 15.2 Sequence of eruption of permanent dentition.

Maxillary teeth	Eruption
Central incisor	7–8 years
Lateral incisor	8–9 years
Canine	11–12 years
First premolar	10–11 years
Second premolar	10–12 years
First molar	6–7 years
Second molar	12–13 years
Third molar	17–21 years
Mandibular teeth	Eruption
Central incisor	6–7 years
Lateral incisor	7–8 years
Canine	9–10 years
First premolar	10–12 years
Second premolar	11–12 years
First molar	6–7 years
Second molar	11–13 years
Third molar	17–21 years

acceptance of, participation in, and satisfaction from their treatment plan, and ultimately success of the treatment.

The importance of the history of the present condition cannot be overemphasized. History of symptoms, trauma, premature or delayed tooth loss, a biopsy, orthodontic treatment, or siblings having similar conditions are examples of factors that will significantly affect the decision-making process. Previous biopsies or symptoms of pain or altered sensation such as anesthesia or paresthesia, are quite important when evaluating pathologic conditions associated with impacted teeth, and may guide the practitioner to perhaps consider another biopsy or surgical evaluation prior to an orthodontic consultation.⁷

A history of trauma may provide interesting clues to the nature of the condition and guide the practitioner to identify factors that can affect the prognosis of different treatment options. Tooth loss and the sequence of eruption can be valuable in the development of timing for the proposed treatment options and may guide the practitioner in the urgency of their intervention.

Medical history is a term often used broadly; it must include past medical history, review of the systems, medications, allergies, past surgical history, and social habits. Initially, this information assists the practitioner to perform a risk assessment for elective procedures, such as routine dental care and oral surgical procedures. However careful examination of this information is helpful in assessing the factors which may have contributed to the specific anomalies such as delayed eruption or malformed teeth. Histories of cleft lip and palate, syndromes, or significant systemic disease processes are important clues in formulation of treatment protocols. Dental practitioners often use various methods to collect medical history; dentists should pay particular attention to the appropriate and accurate collection of this information for evaluating patients with impacted teeth.

Clinical examination should follow a logical format. It is not expected that the dentist will completely alter their usual dental examination; however, a logical emphasis on certain findings is critical. The oral cavity is examined with an emphasis on the condition of the teeth, hard, and soft tissue. Presence of dental caries, gingivitis, or clinical evidence of periodontal disease can greatly impact the prognosis of the proposed therapy. Particular attention should be paid to the condition of the oral mucosa which may provide clues to the possible pathologic conditions associated with the impacted teeth. Presence of a mass, its consistency, and the color of the overlying mucosa are of particular concern. A bony hard mass with overlying mucosa consistent with the surrounding tissue can suggest an expansile bony lesion in this area. However, this should be differentiated from the normal bony bulge or prominence directly over an impacted tooth. This bony prominence itself is quite valuable in planning for surgical flap design. On the

other hand, a rubbery or fluctuant mass may be suggestive of an eruption cyst; the same consistency with pain and erythema may be a sign of an inflammatory process such as pericoronitis. Identification of pathologic findings such as cysts or tumors is critical, since the differential diagnosis of these findings can dictate overall patient management. Large lesions can often irreversibly affect the eruption of a tooth or its long-term prognosis. The treatment may range from a simple biopsy during the surgical exposure to complete resection of the affected area, including the impacted tooth. In all these cases an inclusive differential diagnosis must be formulated and appropriate referral should be made if there is any uncertainty regarding the appropriate management protocols.

Counting teeth, although an effortless part of the oral examination, can be easily overlooked. This simple step often helps to identify occlusal discrepancies, dental midline shift, and the extent of the dental anomaly.

The sequence of eruption, the normal standard deviation, and the patient's developmental age must be observed to differentiate between an expected delay in eruption and pathologic conditions. For example, an overall timely sequence of eruption and no evidence of primary tooth exfoliation in a specific area may indicate the likely need for therapeutic intervention. Similarly, teeth that have not erupted by the appropriate developmental age, within the accepted standard of deviation, may be considered for evaluation and treatment. In the absence of any other findings, a patient with a history of delayed eruption of primary and permanent dentition may be considered a good candidate for observation.

Dental crowding can affect the proper eruption of an impacted tooth into the dental arch and should be a part of patient evaluation, since it can affect the overall orthodontic management of the patient. For example, in a patient with limited arch space and an impacted maxillary canine, the correct sequence of management must be formulated. In these instances, a team approach is needed to manage the arch space deficiency with orthodontic treatment, and then the impacted canine can be surgically exposed to facilitate its guided eruption.

The presence of a retained primary tooth is always a puzzle. It is often unclear whether the primary tooth is retained due to the lack of contribution to its exfoliation from an unerupted permanent tooth, drifting or tilting of the adjacent permanent teeth preventing its exfoliation, pathologic conditions such as ankylosis, or a combination of these factors. Retention of the primary tooth can ultimately affect the treatment sequence and potential outcome.

Radiographic evaluation

The ultimate goal of the radiographic evaluation is to determine the location of the impacted tooth, its rela-

tion to the anatomic structure, and identification of potential pathologic findings in that area. Therefore imaging must provide diagnostic information about the impacted tooth and the surrounding structures. This presents the dental practitioner with the dilemma of what type of radiograph to obtain to provide the most diagnostic information.

Bitewing radiographs have limited value in the treatment planning of impacted teeth, but if available they can be used to assess the position of the tooth in relation to the crest of the alveolar ridge and the cemento-enamel junction of the adjacent teeth.

Periapical radiographs are helpful tools in diagnosis and treatment planning, especially if obtained correctly. A very beneficial aspect of the periapical radiograph is its role in localization of an impacted tooth; this can be achieved by repositioning of the film and the X-ray head and observing the shift in the image produced. This is known as Clark's rule, which can be remembered by the use of the mnemonic SLOB (Same Lingual Opposite Buccal) and is described as follows. The first periapical image is obtained in the standard fashion. A second image is obtained by maintaining the film in the relatively same location and then moving the X-ray head distal or mesial to its previous position. If the image of the tooth moves in the same direction as the X-ray head then the tooth is located on the lingual aspect of the alveolar ridge. If the image moves in the opposite direction of the X-ray head, then the tooth is positioned on the buccal aspect of the alveolar ridge. This is valuable information in surgical treatment planning to access an impacted tooth for removal or exposure. The biggest limitation of this technique is operator error since it is technique-sensitive. Potential problems are improper labeling of the films and inconsistency of the film placement. The personnel obtaining these radiographs should be trained and instructed properly, and preferably use film-positioning devices.^{8,9}

An *occlusal radiograph* is an appropriate imaging tool; if obtained correctly it can be used to confirm the location of the impacted teeth in relation to the adjacent dentition especially in the anterior maxilla and mandible. The disadvantage of occlusal radiographs is obtaining a high-quality and diagnostic image from the posterior region due to difficulty with film positioning and artifact from the nearby anatomic structures.

A *panoramic radiograph* is perhaps one of the most useful images available to the team involved in the patient's care; it can be used to easily identify the location of the impacted tooth and its relationship to the adjacent teeth and relevant anatomic structures. It can also be used as a tool to assess the patient's complete dentition and other pathologic findings that may be present. Some authors have developed strategies based on panoramic radiographs to identify prognostic markers for treatment of impacted canines. The axial position of impacted teeth can be readily estimated based on a panoramic radiograph; this can

impact the overall treatment plan.^{10,11} For more details regarding periapical, occlusal, and panoramic radiograph imaging see Chapter 2.

In recent years, there has been much excitement about the use of three-dimensional (3D) imaging in many areas of dentistry. These images are captured by the use of the same principles as medical grade computed tomography (CT scans) and are known as cone-beam CT; this can be a useful resource in evaluation of patients with impacted teeth. With the use of cone-beam CT the practitioner can identify the exact location and position of the impacted tooth in three dimensions. It provides accurate and useful information regarding the position of the tooth, location of the anatomic structures, and presence of pathologic findings, all of which can be valuable in treatment planning, assigning risk factors, and evaluating prognosis. Some studies have demonstrated a positive correlation between the 3D information regarding the position of an impacted tooth and its response to guided eruption.¹² However, the value and availability of this information, and its impact on patients' overall treatment should be weighed against the resources spent to obtain this information. Practitioners must identify the needs for such images and the impact that they may have on the patients' treatment. In general, cone-beam CT should not be considered a routine imaging modality, rather an adjunct to the information provided by conventional radiographs.¹³ For more details regarding CT scans and cone-beam CT imaging see Chapter 2.

Treatment planning

Indications, risks, benefits, and alternatives must be clearly identified, even though on the initial presentation the indication may appear quite clear. The factors contributing to the lack of eruption, such as lack of arch space, relation to the adjacent teeth, existence of a retained primary tooth, and existence of odontogenic and non-odontogenic pathologic findings, are the main factors that should be considered and can determine the indications for treatment. Other factors to consider include the patient's chief complaint, symptoms, age, and any findings that can identify the impacted tooth as a pathologic entity. These findings may include damage to the adjacent teeth in the form of dental caries, bone loss, recurrent infection, or pericoronitis. Also, impacted teeth can affect patients' overall dental treatment and rehabilitation. For example an impacted canine may result in inability to place an implant in the site of a missing tooth.^{3,4}

Although age in itself is not a deciding factor, it has a potential impact on the indications for treatment. For example an elderly patient with an asymptomatic impacted tooth in the absence of any pathologic findings may be a candidate for observation. On the other hand a teenager with an impacted

premolar should never be considered for an extraction unless an orthodontic evaluation has been performed and guided eruption has been ruled out.¹⁴

Once the indications have been identified, the benefits of the treatment should be communicated to the patient. Patients often assume that they must have treatment for the condition that has been identified; but often the benefits of such treatment, its impact on their overall health, and prognosis of such treatment are not well understood. It is the dentist's responsibility to clarify this information for the patient. The benefits of treating an impacted tooth include guided eruption to create occlusal harmony, improved function, and esthetics. Its removal may be beneficial to alleviate a source of pathology or damage to the adjacent teeth in the form of dental caries or periodontal defects. General practitioners, as well as specialists, must objectively recognize the benefits and prognosis of different treatment options.^{3,4}

Discussion of the risks of the proposed treatment alternatives is quite important. Patients and health care providers often view this discussion as a necessity of our current heightened medical-legal environment. In reality, however, this discussion is designed to be educational in nature and create an objective communication portal to improve the doctor-patient relationship. One must recognize the fact that, generally, litigation is not a result of occurrence of a complication, rather the fact that complications were not acknowledged, recognized, or managed appropriately. The doctor should aim to educate his or her patient to a point of recognizing the risks and complications as factors to contemplate when considering different treatment options. The doctor must not present the risks and complications of the treatment as trivial and inconsequential. Whenever possible, this information should be presented with the support of the most reliable and current evidence available. The risks of removal or exposure of an impacted tooth may include damage to the adjacent teeth, floor of the nose, maxillary sinuses, and neurovascular bundles. Guided eruption may not fulfill its objectives due to ankylosis or instability of the tooth necessitating extraction. Postoperative edema, bleeding, infection, and pain are expected risks of all surgical procedures.^{2,3}

A number of treatment options may be considered for impacted teeth other than third molars. These include observation, extraction, guided eruption, and modification of the existing dentition to allow spontaneous eruption. Observation and no treatment must always be presented as a treatment alternative. As health care professionals we consider direct involvement in our patients' care as an ethical and justified responsibility. However, the patients' right to hear and understand an objective discussion regarding observation as an option is equally justified and ethical. This right has often been enforced by medical-legal jurisdictions and the standards of care. Observation may range from no treatment to a defined

period of clinical and radiographic follow-up to monitor progress or identify pathologic conditions.^{2,3}

Extraction of the impacted tooth often appears to be a justified possibility, however in reality it is generally an option of last resort. Extraction of an impacted tooth is by definition a traumatic procedure with well recognized risks and complications. Although such risks and complications are well justified in presence of objective indications, it is prudent to avoid them if at all possible.

Guided eruption must be considered and thoroughly evaluated in all patients. This statement may further be extended to include patients of all reasonable ages, even though such treatment is often difficult to implement predictably and successfully.¹⁴ A general practitioner may consider recommending an orthodontic consultation for an older individual, if the patient is willing to consider it. Guided eruption is time consuming and often requires involvement of multiple teams in the patient's care. This should be balanced against the patient's expectations and willingness to embark on a complex treatment.

Modification of the existing dentition, realistically, is only applicable to the unerupted teeth that possess eruption potential. This is demonstrated by an unformed apex and teeth that are generally in a correct position to the arch and alveolar crest.

Orthodontic considerations and prognostic markers

In order to offer the best treatment option to the patient, there must be an attempt to identify the difficulties associated with and the prognosis of the proposed treatment. Many authors have attempted to produce treatment difficulty indices for unerupted teeth planned for guided eruption. The factors that have demonstrated greatest impact upon the success of the management of impacted maxillary canines include angulations of canine to the midline, age of the patient, vertical height, and bucco-palatal position.¹¹ These factors can also affect the duration of the treatment. An increase in the number of patient visits has been reported in patients aged 25 and older, when the cusp tip is farther from the occlusal plane, when the cusp tip is mesial to the axes of the lateral incisor, and where the tooth is less vertically inclined. In a study performed by Becker *et al.*, the treatment of impacted maxillary canines was successful in 100% of patients aged 12–16 years, compared with 69.5% in patients aged 20–47 years. In this study all the failed canines were in the patients aged 30 years and older.¹⁴ Therefore it is imperative for the clinician to promote an objective expectation for their patients in regards to the success and prognosis of their treatment. Similar prognostic markers may be stipulated for the management of all impacted teeth other than third molars.

Surgical considerations and prognostic markers

In addition to the factors affecting the successful guided eruption of impacted canines the practitioner must consider surgical implications of the treatment. Patients' tolerance for surgical procedures including management under local anesthesia versus intravenous sedation should be considered. The surgical flap and removal of bone to expose the impacted tooth may compromise the adjacent dentition and vital structures. The nature of the surrounding bone, keratinized gingiva vs non-keratinized mucosa, condition of the impacted tooth, and its relation to the roots of the adjacent teeth must be evaluated under direct vision. This information is valuable and it helps the other members of the team, e.g. orthodontist, if it is documented by the use of intraoperative photographs.

Surgical management

After thorough evaluation, treatment planning, and discussions with the patient and other team members, the surgical treatment of the impacted tooth can be planned accordingly. A critical factor in this phase of the patient's care is timing of the surgical procedures. For guided eruption of an impacted tooth, it is generally expected that the patient will undergo an initial phase of orthodontic treatment. The orthodontic treatment can range from basic bracketing and stabilization of the adjacent teeth to complete leveling and alignment of the dental arches. The primary purpose of presurgical orthodontic treatment is to create adequate arch space to facilitate the eruption of the impacted tooth. In certain cases with the proper alignment of the teeth and creation of adequate arch space, an unerupted tooth may only require surgical exposure to relieve the affect of the soft tissue on the delayed eruption. However, in many cases the surgical objective is indeed to surgically expose and bond an attachment to facilitate guided eruption of the impacted tooth.^{2,15,16}

Presence of a retained primary tooth, although not terribly critical to the management of the impacted tooth, may be an important factor to the patient, especially from the esthetic point of view. Patients are often quite satisfied with bonding of a denture tooth to their orthodontic wires. This simple and small step can significantly impact the patient's esthetic needs, acceptance, and satisfaction with their treatment.

Surgical removal

If removal of the impacted tooth is planned, a number of issues must be considered. Regardless of the radiographic position or appearance, the practitioner should plan this surgery as removal of a full bony

impacted tooth in terms of instrumentation and time allowance. A full-thickness mucoperiosteal flap should be planned. It is desirable to make an intersulcular incision extending to at least one to two teeth in each direction from the area of interest (Fig. 15.1). This will allow adequate retraction of the flap and proper visualization. A common error is to develop a small flap and extend it conservatively. This approach, although reasonable in theory, in practice often leads to tearing of the flap and/or inadequate exposure, ultimately resulting in a poor outcome. A well planned and properly retracted large flap generally heals as well, if not better, than a traumatized small flap.

Vertical release of the flap, although acceptable, must be carried out quite carefully. Improperly positioned vertical release can cause poor soft tissue outcome, in the form of recession and unesthetic gingival margins. One must attempt to position a vertical release on the line angle or in an edentulous area. A vertical release must never be placed on the midline of a tooth. Extension of the flap and location of any releases should be planned very carefully with respect to the anatomic regions. For example a vertical release should not be placed in the region served by the mental nerve, as it may transect the fairly superficial branches of this nerve resulting in sensory disturbances. Another example is the posterior mandible distal to the first molar region. An incision in this area must extend laterally from the surgical site toward the lateral oblique ridge (Fig. 15.2). This design greatly reduces the risk of damage to the lingual nerve, which in some instances can be located near the crest of the alveolar ridge distal to the second molar.

Upon dissection of the flap and exposure of the impacted tooth, adequate bony decortication must be carried out to expose the tooth. The attempt to remove these teeth whole is often not fruitful. Therefore, well planned sectioning of the impacted tooth is often needed. An important point that must be emphasized is the use of a surgical drill rather than a dental hand-

Fig. 15.1 Exposure of a buccally positioned maxillary canine using a full-thickness mucoperiosteal flap. Intersulcular incision and subperiosteal dissection has been performed to develop this flap.

Fig. 15.2 An illustration of the incision to expose an impacted second molar in the posterior mandible. The distal portion of the incision is positioned laterally to avoid potential damage to the lingual nerve.

piece. Dental handpieces often spray an air–water mixture which can result in collection of air under the soft tissue flap, forming an air emphysema which can become potentially life threatening. Once the impacted tooth is removed whole or in sections, the surgical site can be closed primarily.

Exposure and bonding for guide eruption

Different approaches may be considered, if the impacted tooth is planned for exposure and bonding of a bracket. In this circumstance, one of the most important factors in surgical planning is buccal and palatal position of the tooth; the surgical approach is quite different for the two scenarios. If the tooth is positioned buccally, great care must be taken to maintain adequate keratinized and attached mucosa over the tooth. The presence of attached mucosa is absolutely critical to the health and prognosis of the soft tissue around the erupted tooth. An apically positioned soft tissue flap is an appropriate flap design when planning to expose and bond a buccally positioned impacted tooth. An apically positioned flap is designed as a full-thickness mucoperiosteal flap starting from the crest of the alveolar ridge with an adequate amount of attached mucosa. The flap is mobilized by creating vertical releasing incisions on each side; subperiosteal dissection is then carried out to the level of cemento–enamel junction of the erupted tooth. At this point the dissection plane is changed to the superperiosteal plane and the flap is further mobilized. Bone overlying the unerupted tooth is removed to facilitate bonding of a bracket. Upon completion of the bonding the flap is positioned apically at the cemento–enamel junction

and sutured to the periosteum.¹⁶ Some practitioners advocate placement of a periodontal dressing such as PerioPack™ over the exposed crown to limit the soft tissue overgrowth. Although it seems a reasonable idea, there has been no evidence supporting its routine use and positive impact upon the overall patient care. It is generally accepted as anecdotal and personal preference by practitioners.

If the tooth is positioned palatally, the development of a soft tissue flap is quite straightforward; however it is quite cumbersome due to the patient's position and tenacity of the palatal tissue. The best patient position is in a supine or slight Trendelenburg position which requires considerable attention for a patient who is under moderate to deep sedation. Once the flap is reflected, hemostasis to achieve a field dry enough for bonding is the biggest challenge. Although frank bleeding is not common, the slow oozing of the tissue can be a nuisance and hinder visualization of the tooth and bonding of the bracket. The oozing is best controlled by infiltration of local anesthesia containing a vasoconstrictor throughout the planned flap or packing with gauze or cotton pellets soaked in local anesthesia or an epinephrine solution. The bone overlying the impacted tooth is at times quite thin and may be removed with a hand instrument such as a periosteal elevator. Otherwise a round bur on a surgical handpiece can be quite effective. Care must be taken to not remove bone in a manner that might compromise the crown of the impacted tooth or the adjacent teeth. The overlying bone can be removed conservatively, and often it is not necessary to remove all the bone overlying the crown of the impacted tooth, but at times this does provide better visualization and access for bonding. If possible, a path for eruption should be created by conservative decortication of the palatal bone extending from the crown of the impacted tooth toward its planned location.

Once the crown of the tooth is exposed the next step is bonding of the bracket. For this purpose the site should be kept dry and free of blood. Again packing of the site with a gauze or cotton pellet soaked in epinephrine solution or infiltration of local anesthetic containing vasoconstrictor may be helpful to maintain the bonding site dry. A bracket or button attached to a chain or ligature wire is bonded to the crown of the impacted tooth (Figs 15.3, 15.4). Ligation of the impacted tooth with ligature wire or other methods is no longer an acceptable technique and may readily result in complete failure of the treatment. Auto- or light-cure bonding agents are used following the sequence recommended by the manufacturer. There are many bonding agents and orthodontic brackets commercially available specifically for bonding and bracketing of impacted teeth. Although it is not always possible to achieve, the ideal location of the bonded bracket is the most incisal portion of the crown. This position provides the most favorable application of orthodontic forces and best mechanical

Fig. 15.3 Exposed crown of an unerupted maxillary canine. Bony defect around the crown of the impacted tooth is due to the dental follicle.

Fig. 15.4 A bracket and gold chain have been attached to the buccal surface of the impacted tooth. The excess bonding material should be cleansed from the tooth to reduce tissue irritation.

advantage needed to move the impacted tooth into the desired position.

Once the tooth is successfully bonded, soft tissue closure of the flap can be performed. The flap can be closed primarily or alternatively the overlying mucosa can be excised and the wound packed with wound dressing such as PerioPack or Iodoform gauze. Soon after recovery patients may continue orthodontic treatment.

Antibiotic use is often unnecessary postoperatively. Patients may experience moderate to severe pain for the first and second day which can be relieved with prescribed analgesics. Orthodontic manipulation is initiated after the initial healing of the soft tissue and when the patient is comfortable, which can usually be expected 7–14 days after the surgery.

Postoperative management and complications

The postoperative events and complications associated with exposure of impacted teeth are generally similar to those from other dentoalveolar surgical procedures.² Patients can experience postoperative pain, edema, bleeding, wound dehiscence, and infection. Effective pain management is quite appropriate after this type of surgical procedure. Additionally, the use of soft diet and oral wound care may improve patient comfort and reduce wound dehiscence. Limited data are available regarding the incidence of postoperative infection after exposure of impacted canines and premolar teeth. However, it may be safe to extrapolate the data from the third molar studies which report the incidence of postoperative infection to be approximately 0–12%.^{17–19}

The complication most specifically associated with exposure of impacted teeth is the failure of the initial bond or debonding of the bracket from the exposed tooth. This has been reported to range from 1–5% and has been attributed to failing to obtain a dry field during the bonding process.¹⁹ Postoperative debonding is a serious problem; at times it can be quite difficult to remedy for the surgeon, and traumatic for the patient as they may have to undergo a secondary surgical procedure. Therefore it is quite critical to not only ensure successful bonding of the bracket initially, but also to test this bond critically prior to closure of the wound. This can be simply achieved by applying a gentle yet persistent traction on the chain attached to the bonded bracket after complete curing of the bonding agent. In the event of bond failure or the need for rebonding the cured material should be cleaned from the tooth and bracket thoroughly. When there is a failure of the initial bond, the material may be scraped off and the tooth may be etched and bonded again.^{20,21} Cleaning partially cured bonding agent from a debonded bracket is awkward and time consuming, although it can be achieved by the use of a sand blaster. The use of a new bracket may be more appropriate and less time consuming. Reattaching a bracket after a postoperative debonding is somewhat more cumbersome since the tooth may have to be re-exposed. This can be performed successfully by the use of some of the more specialized etching and bonding agents.^{20,21} However, simply removing the cured bonding agent from the surface of the tooth using a diamond bur or gentle strokes of a carbide bur, and rebonding a new bracket to the tooth in a dry field is equally rewarding.

Chapter 16

Nerve Involvement in Oral and Maxillofacial Surgery

M. Anthony Pogrel

This chapter describes the prevention, diagnosis, evaluation, and management of injuries to the inferior alveolar nerve, lingual nerve, long buccal nerve, mylohyoid nerve, and facial nerve as a result of oral and maxillofacial procedures. Nerve damage from inferior alveolar nerve blocks, dental implants, root canal therapy, and dental alveolar surgical procedures are described, as well as the semi-objective evaluation techniques that can be used in connection with these injuries. Work on objective evaluation techniques is also described. The management of these injuries, including microneurosurgical procedures, is discussed.

Trigeminal nerve

Injury to the terminal sensory branches of the trigeminal nerve (the lingual nerve, the inferior alveolar nerve, and the long buccal nerve) is relatively frequent and can occur as a result of many different forms of dental treatment.¹

Inferior alveolar nerve block

It is known that both temporary, and occasionally permanent, nerve damage can occur as the result of an inferior alveolar nerve block.² The nerve predominantly affected appears to be the lingual nerve, which is affected approximately twice as often as the inferior alveolar nerve. The incidence is unknown with esti-

mates of permanent nerve damage resulting from inferior alveolar blocks varying from 1 in 20 000 inferior alveolar nerve blocks to 1 in 850 000 inferior alveolar nerve blocks. Transient damage from inferior alveolar nerve block (those recovering even if they take up to 9 months to do it) probably occurs five or six times as frequently. The reason for the predominance of lingual nerve injuries is unknown; it could possibly be related to the relative fascicular pattern of the nerve in the area of the lingula, since in this area the lingual nerve may be unifascicular in up to one third of cases, which may make it more liable to be damaged.³ The exact cause of injury with an inferior alveolar nerve block is unknown, but suggestions have included direct trauma from the needle in some way, hematoma to the nerve, or a neurotoxic effect from the local anesthetic itself. The fact that these patients appear to have a high proportion of dysesthesia (over 30% of such patients suffer from dysesthesia compared with only 8–10% of patients having nerve involvement as a result of third molar extraction) and a somewhat different pattern of recovery suggests that a mechanism other than simple trauma may take place. All local anesthetics appear to have the ability to cause this problem, though there may be some variation between the local anesthetics.⁴

Treatment is symptomatic; most cases recover within an 8–10 week-period, and a smaller number recover over a 9-month period. About 10% of cases prove to be permanent, with occasional disabling dysesthesia.

Inferior alveolar nerve damage from root canal treatment

Root canal therapy carried out on lower molar teeth has the ability to damage the inferior alveolar nerve either from direct trauma from overinstrumentation, from a hydrostatic pressure phenomenon, or neurotoxicity from extruded root canal sealant (Fig. 16.1).⁵ All root canal sealants appear to be neurotoxic, the only differences appear to be in the time they need to be in contact with the nerve to cause damage. Those

Fig. 16.1 Extruded root canal sealant in the inferior alveolar canal.

containing paraformaldehyde, or an analog, may cause damage almost immediately, whilst less toxic sealants, such as eugenol or calcium hydroxide (because of its high pH), may not cause damage until they have been in contact with the nerve for 24–72 hours. The incidence of this complication is unknown, but a paper describing 61 cases suggests that early surgery (preferably carried out the same day as the injury to remove any sealant from around the nerve) may be successful.⁵ Otherwise, these injuries tend to be permanent, with a relatively high incidence of dysesthesia, and respond relatively poorly to surgery carried out at a later date.

Nerve damage from dental implants

The insertion of osseointegrated implants into the mandible has the potential to damage the inferior alveolar nerve and mental nerves due to overextension (Fig. 16.2).^{1,6,7} In this case, the injury may be related to drilling prior to implant insertion, particularly since most drills are 0.5–1.5 mm longer than the implant that will be fitted (Fig. 16.3). Accurate measurement of the amount of alveolar bone available to place implants is necessary and plain radiographs are

Fig. 16.2 Implants impinging on the inferior alveolar nerve.

Fig. 16.3 (a) Radiograph of implant appearing not to impinge on the inferior alveolar nerve. (b) Radiograph showing that the drill used to prepare the implant site was longer and did impinge on the nerve.

often supplemented by cone-beam computed tomography (CT) scans to gain an accurate impression of the amount of bone available (Fig. 16.4). If there is anesthesia or paresthesia of the inferior alveolar nerve following implant insertion once the local anesthetic has dissipated, consideration should be given to obtaining a cone-beam CT scan to accurately relate the position of the implant to the nerve, and early consideration should be given to shortening or removing the implants. This can be successful in the early stages when the involvement is due to pressure alone from the implants or hydrostatic pressure. However, many cases do not recover, presumably since the damage is more profound or was caused by the twist drill. The authors have explored a number of these cases and have found that the injuries were

Fig. 16.5 An implant placed anterior to the mental foramen which has damaged the mental nerve as it loops back to the foramen.

Fig. 16.6 Twist drill for implant site preparation with a stop on it prevent overdrilling in the posterior mandible.

often so profound that they were either impossible to repair or they could only be repaired with a graft, which does not give good results. Therefore, at present, it is probably only advisable to explore cases where there appears to be a realistic chance of improving the condition. Cases can occur from implants inserted anterior to the mental foramen if consideration is not given to forward looping of the inferior alveolar nerve before it exits the mental foramen. Although implants are normally placed sufficiently anterior to the mental foramen to avoid this loop of inferior alveolar nerve, on occasions it can be visualized from the radiographs⁸ and additional space needs to be allowed (Fig. 16.5). Most implant systems come supplied with a stop of some kind to avoid overdrilling, which may inadvertently involve the inferior alveolar nerve (Fig. 16.6). These stops should be used when available to limit drill penetration to the predetermined length only.

Periodontal surgery

Periodontal surgery in the form of the distal wedge procedure (Fig. 16.7) and extensive surgery or deep root planing on the lingual side in the lower molar region can cause damage to the lingual nerve,¹ particularly when the nerve lies in an aberrantly superior position as is known to occur in between 15 and 20% of cases.⁹ In these cases the nerve can lie at the level of the crest of the lingual alveolar bone or even slightly above it. Studies have shown that in the majority of cases the lingual nerve lies around 8mm below the crest of the alveolar ridge and some 2–3mm lingual to the lingual plate and would not be at risk from normal periodontal procedures. If periodontal surgery is to be performed in these areas, the surgeon must have knowledge of the possible aberrant positions of the lingual nerve and take this into account when performing the surgery. If the nerve is damaged with a sharp instrument such as a scalpel, early surgical nerve repair may give satisfactory results.

Fig. 16.7 Diagram to show how a distal wedge-type procedure can damage the lingual nerve if it lies in an aberrantly high position.

Nerve damage from dentoalveolar surgery

Dentoalveolar surgery carried out on the posterior mandible can cause damage to the lingual nerve, the inferior alveolar nerve, the long buccal nerve, and even the mylohyoid nerve. The commonest dentoalveolar procedure carried out in this area is third molar removal, but other surgical procedures in this area have the potential to cause damage.¹

The incidence of inferior alveolar nerve damage from the removal of third molars varies in the literature from 0.5–5%.¹⁰ The cause is directly related to the anatomical relationship between the inferior alveolar nerve and the roots of the third molar. In many cases, this can be determined from panoramic type radiography, and criteria have been developed to determine more exactly from a panoramic radiograph the relationship of the inferior alveolar nerve to the tooth.¹¹ This is shown in Fig. 16.8. When the image of the inferior alveolar canal is superimposed over the tooth with no loss of lamina dura of the canal and no narrowing or change of direction, the relationship is probably one of superimposition with a low risk of nerve involvement as shown in Fig. 16.8a. If, however, the nerve loses its lamina dura it may in fact be grooving the tooth, and the risk of inferior alveolar nerve involvement on removal of the tooth may be higher. This is shown in Fig. 16.8b. Fig. 16.8c shows loss of the lamina dura, narrowing, and possible deviation of the path of the inferior alveolar canal and denotes an intimate relationship between the tooth and the nerve with a high risk of nerve involvement that may be 50% or higher. A pair of periapical films, taken at different angulations, may reveal relationships between the roots and nerves, by applying the parallax principle (“same lingual, opposite buccal”). Cone-beam CT technology can now accurately show the relationship of the inferior alveolar nerve to the third molar in three dimensions^{12,13} and this has

Fig. 16.8 Diagram to show the relationship of the inferior alveolar nerve to the roots of a mandibular third molar as seen on a panorex radiograph. (a) Superimposition only with no loss of cortical outline, narrowing or deviation. (b) Loss of cortical outline denotes grooving of the roots by the nerve. (c) Loss of cortical outline, narrowing, and deviation denote an intimate relationship between the nerve and roots of the third molar. (From Pogrel MA. Complications of third molar surgery. *Oral Maxillofac Surg Clin N Am* 1990; 2: 441–51. With permission. Copyright © 1990 Elsevier.)

helped to quantify the issue of the risk involved in the removal of such teeth (Fig. 16.9). Where suitable imaging shows an intimate relationship between the roots of the third molar and the inferior alveolar nerve, a decision must be made whether to proceed with the removal or not, or possibly consider intermediate strategies varying from orthodontic forced eruption of the teeth away from the inferior alveolar nerve prior to extraction¹⁴ or possible coronectomy or partial tooth removal (Fig. 16.10) whereby the portion of the root intimately related to the inferior alveolar nerve is left behind.^{15,16} For this technique to be successful the patient needs to be placed on antibiotics prior to the removal so that antibiotics are in the pulp chamber of the tooth when it is removed, the retained roots need to be at least 3mm below the level of the surrounding alveolar bone so that bone can heal over them, and primary closure of the socket (coupled with periosteal release, if necessary) must be carried out. Lingual retraction is necessary in these cases to avoid damage to the lingual nerve when the crown is sectioned. Studies show that this is a safe and predictable technique with a high success rate in avoiding injury to the inferior alveolar nerve, although some of the roots may later move and some may even require subsequent removal.^{15,16}

Lingual nerve

Lingual nerve injuries in relation to dentoalveolar surgery are less frequent than inferior alveolar nerve injuries. Frequencies have been quoted as occurring in 0.2–2% of all lower third molar removals, although they do appear to be more troubling to patients.¹⁷ In most cases the lingual nerve is protected beneath the lingual plate of bone, as it lies approximately 6–8 mm inferior to the lingual crest and some 2 mm medial; studies have shown, however, that in between 15 and 20% of cases the lingual nerve may lie at or above the level of the lingual plate and is therefore at risk during third molar removal.¹⁷ It is felt that it may be at risk:¹⁷

- during the initial incision if it is made too far lingually and the patient has an aberrant lingual nerve;
- during flap retraction if a lingual flap is raised with a misdirected or sharp instrument and the lingual nerve is in an aberrant position;
- the lingual split technique, if used to remove lingual bone prior to removal of third molars, can damage the lingual nerve either by the lingual flap retraction or by sharp edges of the bone itself;
- removal or fracture of lingual or distal bone during removal of the tooth can damage the lingual nerve;
- tooth sectioning, if the drill is placed too deeply and penetrates the lingual plate of bone;

Fig. 16.9 (a) Example of a case where the shadow of the mandibular canal loses its cortical outline, narrows, and is deviated, denoting an intimate relationship between the nerve and the tooth root, which was confirmed on coronal CT (b) and on subsequent tooth removal where the tooth has been grooved by the nerve (c).

Fig. 16.10 (a) Coronectomy preoperative. (b) Clinical at time of surgery with retained root of lower left third molar 3mm below the crest of the alveolar bone. (c) Immediate postoperative radiograph. (d) Radiograph taken 6 months later showing coronal migration of the retained roots with bone over them and no pathology present.

- overaggressive removal of retained dental follicle on the lingual side may damage an aberrantly placed nerve;
- deep suturing may damage an aberrantly placed lingual nerve on the lingual side of the incision;
- in some cases the lingual plate of bone may be absent congenitally or due to infection or other pathologies, and the lingual nerve may be in direct contact with the tooth and therefore at considerable risk when the tooth is removed.

Fig. 16.11 denotes recommended incisions for the removal of a lower left third molar, which should not endanger the lingual nerve. Fig. 16.12 demonstrates the problem of retained dental follicle adjacent to an aberrantly placed lingual nerve, whilst Fig. 16.13 demonstrates that sutures placed too deeply can damage the lingual nerve; sutures should be placed very superficially. Lingual flap elevation and the placement of a subperiosteal lingual retractor is an acceptable technique in order to protect the lingual

Fig. 16.11 Recommended incisions for removal of a lower third molar. (a) Triangular flap with buccal release. (b) Gingival margin envelope flap. Note that both incisions are buccally placed.

Fig. 16.12 Diagram to show how an aberrantly positioned lingual nerve can be attached to remnants of the dental follicle, which should be removed with caution.

Fig. 16.13 Diagram to illustrate how deeply placed sutures following third molar removal can endanger an aberrantly placed lingual nerve. Sutures should be superficial only, or the sockets should be packed without suturing.

nerve during third molar removal if it is anticipated that bone will need to be removed in the distal or disto-lingual areas or if the crown must be totally sectioned. It is accepted that there is a small risk of transient nerve involvement following the use of lingual retraction, but this virtually always recovers spontaneously in a few weeks.¹⁷

Long buccal nerve

Considering the anatomy of the long buccal nerve (Fig. 16.14), it might be anticipated that this nerve would be involved in many cases during third molar removal.¹⁸ However, it is unusual for patients to be aware of damage to this nerve, partly because they are unaware of the altered sensation on the inner aspect of the cheek, and often because there is an overlapping nerve supply from surrounding nerves. Nevertheless, damage has been documented on a number of occasions and can occasionally be trouble-

Fig. 16.14 Diagram to illustrate the usual position of the long buccal nerve which is at risk with any extended incision for third molar removal.

some to patients.¹⁹ In practice, it is virtually impossible to find the long buccal nerve surgically, and equally impossible to repair it.

Mylohyoid nerve

Involvement of the mylohyoid nerve has been reported in up to 1.2% of third molar removals but is normally associated with lingual retraction, where the retractor has been placed too deeply.²⁰ There is generally a localized area of paresthesia beneath the point of the chin on the affected side. It has been suggested that the mylohyoid nerve may provide part of the nerve supply to the tip of the tongue, possibly explaining different manifestations of nerve damage on the tip of the tongue versus other parts of the tongue.²¹ Involvement of the mylohyoid nerve is usually temporary and of little clinical significance.

Evaluation of trigeminal nerve damage

Most evaluation techniques for nerve involvement are semi-objective at best and do rely on the presence of a cooperative patient.²² The different testing techniques are used to evaluate the different types of nerve filaments that might be involved. In all cases the normal side is tested first and the abnormal side is compared to it. Semmes-Weinstein plastic filaments (often called Von Frey's hairs after the original such system which used different thicknesses of horse hair) (Fig. 16.15) or its equivalent are used to test sensation quantitatively, and since the numbers applied to the filaments represent the reciprocal logarithmic value of the weight in grams that it takes to bend the filament, this results in a straight line graph of the force required to detect the sensation. Two-point discrimination is used to qualitatively detect sensation in the larger nerve filaments, whilst temperature sense and direction sense can also be evaluated. Temperature sensation can be tested with Minnesota

Fig. 16.15 (a) Semmes-Weinstein filaments (Von Frey's hairs) for quantitatively testing sensation. (b) Use on a patient to map out the affected area. Filaments should be pushed into the tissue and not stroked along it as this can test direction sense and give erroneous results.

Thermal Conductivity Discs or with ice and warm water, and direction sense can be tested with a cotton wisp or the Semmes-Weinstein filaments. By a combination of these means, one can map out the area involved and the degree of involvement within that area. Taste is transmitted via the chorda tympani, which is technically the pretrematic branch of the facial nerve, but it does "hitchhike" within the same overall epineurial sheath as the lingual nerve when it joins it shortly after the third division of the trigeminal nerve exits the foramen ovale and divides into the lingual and inferior alveolar branches. Taste is normally tested with fairly crude dropper bottles containing the four basic tastes (salt, sweet, bitter, and sour), which are tested on the different parts of the tongue without allowing the tongue to come in contact with other taste buds in the mouth (Fig. 16.16).

More objective sensory testing facilities have been evaluated including somatosensory evoked potentials (SEP),^{23,24} magnetic resonance imaging (MRI),²⁵ and magnetic source imaging (MSI).²⁶ SEP have been extremely difficult to reproduce and to standardize and are not used clinically. MRI has not been shown to be able consistently to identify a nerve the size of the lingual nerve. It may, however, be able to identify a moderate to large neuroma forming on a damaged nerve, since the neuroma may be two to three times the diameter of the original nerve, and may appear brighter than the surrounding nerve on MRI scanning. A magnetic resonance technique to enhance nerve visualization, which has been termed magnetic resonance neurography, may cause some enhancement, but still cannot consistently identify the lingual nerve. MSI, particularly superimposed on MRI scans, can give an absolute indication of a totally severed nerve, but it is unclear whether it can detect different degrees of nerve injury. Also, MSI is experimental and only available in a small number of centers. For taste, electrogustometry is available and can give a more objective measure of altered taste.²⁷ Mapping of the area affected and recording photographically can

Fig. 16.16 A typical taste testing kit but with dropper bottles of the primary tastes.

be of help in documenting cases of nerve injury and determining whether recovery is occurring.

Facial nerve

The facial nerve, or VII cranial nerve, is the motor nerve which innervates the muscles of facial expression. It is at risk in a variety of oral and maxillofacial surgery procedures, mostly from procedures performed from an extraoral approach. The only time it is at risk from intraoral procedures is from an inferior alveolar nerve block, the local anesthetic injection technique commonly used to anesthetize the hemimandible, when the needle is incorrectly positioned and the local anesthetic is deposited posterior to the mandible in the parotid tissue where it can permeate to affect the branches of the facial nerve (Fig. 16.17). In this case, there will be a facial nerve weakness which should be transitory and last as long as the local anesthetic effects last (Fig. 16.18). However, long-lasting, if not permanent, cases of facial nerve involvement have been described from this particular procedure, for which no active treatment is available.^{28,29}

Fig. 16.17 Diagram to show how an inferior alveolar nerve block can affect the facial nerve if the local anesthetic is given too far posterior and the needle does not contact bone: (a) normal, (b) injection into parotid gland where facial nerve can be affected.

Fig. 16.18 Transient facial nerve weakness from an inferior alveolar nerve block.

On the face, the main trunk of the facial nerve emerges from the stylomastoid foramen and travels forward and laterally into the parotid gland, where it normally divides into an upper and lower trunk, which further subdivide into the five terminal branches, but there are many variations on this. The zygomaticotemporal, frontal, and buccal branches arise from the upper trunk, while the mandibular and cervical branches emerge from the lower trunk. As they exit the parotid gland anteriorly, they lie in relation to the investing fascia of the neck, deep to the

Fig. 16.19 Relationship of the branches of the facial nerve to the underlying bony structures. X = 0.8–3.5 cm.

platysma muscle. In this position they are at risk in many of the incisions and procedures carried out on the face. All of the branches are particularly at risk during parotid surgery, and this is described elsewhere in this textbook. Similarly, the upper branches (particularly the zygomaticotemporal branch) are at risk during temporomandibular joint surgery, particularly if the dissection is carried forward on the arch of the zygoma in the region of the articular eminence. The anatomy of the facial nerve is variable in this area, and has been described as being anywhere from 0.8–3.5 cm anterior (mean 2.0 cm) to the anterior cavity of the external auditory meatus (Fig. 16.19).³⁰

In the retromandibular approach to the mandible for exploration and fixation of condyle neck fractures, the dissection is normally carried out bluntly between the two main trunks of the facial nerve,³¹ and although damage in this area is possible, it is actually quite unusual.

In the submandibular approach to the submandibular salivary gland and the mandible, both the mandibular and cervical branches of the facial nerve are at risk. The mandibular branch supplies the orbicularis oris, causing a weakness of the corner of the mouth, while the cervical branch supplies the platysma. An involvement of this nerve branch can also cause weakness of the corner of the mouth, though it is usually less severe than with mandibular branch involvement and is often transitory. The studies by Ziarah and Atkinson have shown the positions of these two nerves and where incisions need to be placed in order to avoid them.^{32,33} In 53% of cases, the mandibular branch of the facial nerve does travel below the lower border of the mandible, but never more than 1.2 cm below the lower border, and it has always crossed above the lower border of the mandible by the time the second bicuspid area is reached. Therefore, an incision placed 2 cm, or one finger's breadth, below the angle of the mandible should avoid the mandibu-

Fig. 16.20 Diagram to show the different types of microsurgical procedures possible. (a) Decompression for a localized compression from fibrosis, scarring or a bone fragment. (b) Direct anastomosis for a localized transection, or other injury. (c) A graft to repair a more extensive injury. (From Pogrel MA, Kaban LB. Injuries to the inferior alveolar and lingual nerves. *Cal Dent J* 1993; 21: 50–4. With permission. Copyright © 1997 California Dental Association.)

lar branch of the facial nerve at all times. The cervical branch, however, runs progressively inferiorly as it progresses anteriorly, and in order to avoid contact with this nerve the incisions need to be placed 4 cm below the lower border of the mandible in the mandibular notch area, although 3 cm below the mandible at the angle is sufficient to avoid involvement of this branch. Both of these approaches are feasible for sub-mandibular access surgery.

If these peripheral branches of the facial nerve are damaged during surgery, it is normally not possible to identify or repair them and spontaneous recovery is often incomplete. Surgical repair and reconstruction of the main trunk and the upper and lower branches of the facial nerve may be possible on some occasions, but the results of surgery are generally less than satisfactory.

Microneurosurgery

Microneurosurgery has been attempted to repair injuries to the lingual and inferior alveolar nerve, but

it is normally felt to be impractical for the long buccal, mylohyoid, and chorda tympani nerves. Most authorities feel that it is not possible to restore taste surgically, since there is normally end-organ degeneration after some 3 weeks and the taste buds will not recover. Nevertheless, there are reports of microneurosurgery, carried out up to 6 months after injury, which has restored some taste.^{34,35} Conceptually, the type of nerve injuries that might be treated surgically would include compression injuries where decompression might result in a cure, and partial or complete severing of the nerve (Fig. 16.20). In these latter cases excision of the affected area of nerve is normally required, freshening up of the ends, and direct epineurial repair when this is possible (Fig. 16.21). Undue stretching or devascularization of the nerve should be avoided, and in cases where direct apposition is not possible, a nerve graft or conduit must be used. Donor sites for nerve grafting can come from the great auricular nerve in the neck or the sural nerve behind the lateral malleolus of the ankle (Fig. 16.22); the medial antebrachial nerve of the forearm has also been described as a donor. Conduits have also been

Fig. 16.21 Direct epineurial repair for a recent (within 10 days) transection of the lingual nerve. (a) After exposure showing the two nerve ends. (b) After direct anastomosis with five 8/0 nylon sutures.

Fig. 16.22 Sural nerve graft taken from behind lateral malleolus of the right ankle.

described rather than using a nerve graft, and vein grafts are an autogenous conduit which has met with some success (Fig. 16.23),³⁶ whilst alloplastic conduits such as Dacron have not been shown to be successful.³⁷

Most authorities do feel that if surgery is to be successful, it should probably be carried out within a few months of the injury. The longer one waits the more chance there is of degeneration of the distal segment of the nerve and neuroma formation on the proximal segment, which would need excision and would complicate any repair procedure. Many authorities would feel that surgery was not indicated if the patient has protective reflexes, which occur at about 30% of normal feeling.³⁸ If protective reflexes are present, then it is felt that the patient can protect themselves from further damage. Reports of results of microneurosurgery on the terminal branches of the third division of the trigeminal nerve are few, but do suggest that if surgery is carried out early on patients who do not have protective reflexes between 4 and 7 months after the injury occurring, then there can be some improvement in over 50% of cases, although virtually no cases return to normal.^{39–42} Other reports have suggested that nerve repairs carried out as late as 47 months after the injury can result in some success.⁴³ Repairs are normally performed under magnifying loupes or an operating microscope at magnifications of between 4 and 20 times and the use of 8/0 or 9/0 atraumatic nylon sutures. Four to six epineural sutures are normally placed.

The author's current protocol is to recommend immediate microneurosurgical repair (within 3–7 days) for a witnessed total transection, particularly of the lingual nerve, where the ends tend to retract and spontaneous recovery is rare, and also those cases with symptomatic endodontic paste within the inferior alveolar canal. Surgical exploration is also offered at 8–10 weeks postinjury, in those patients who are either totally anesthetic, or have severe dysesthesia, even in the absence of a witnessed transection. For other patients who have less than 30% of normal sensation (i.e. they lack protective reflexes) or have dysesthesia at 4 months, exploratory surgery may be

Fig. 16.23 Use of vein graft to reconstruct nerve. (a) A neuroma on the right inferior alveolar nerve – extra oral approach. (b) A facial vein graft used to reconstruct the inferior alveolar nerve.

offered at that time, but the results of surgery are poor.

Surgery appears to have little to offer for nerves injured by local anesthetic injections or by implant-related procedures; in the latter case the area of damage is often extensive and may require a graft.

Autotransplantation of Teeth

Lars Andersson, Mitsuhiro Tsukiboshi, and Jens O. Andreasen

This chapter describes autotransplantation of teeth which is a treatment alternative for replacing congenitally missing teeth and teeth lost due to trauma or disease by moving a tooth or a root to a more suitable position within the same individual. This chapter will give an overview of important principles for case selection, surgical technique, and tissue healing which are prerequisites for a successful result. Different situations when autotransplantation can be an advantageous alternative are presented.

Introduction

Transplantation of teeth has been performed for many centuries.^{1–3} Earlier in history teeth were transplanted from one man to another, so called allotransplantation. This always resulted in a limited survival of the transplant and high failure rate due to immunogenic reactions destroying the periodontal ligament (PDL), resulting in root resorption and loss of the transplant.^{4,5} There is also a risk for transmission of diseases between individuals.

However there are numerous clinical studies during the past decades showing that teeth can be transplanted with good prognosis within the same

individual, so called autotransplantation.^{3,6–67} Experimental research carried out in recent decades has given us knowledge to better understand wound healing following autotransplantation.^{68–79} Autotransplantation of a tooth can be defined as a tooth extracted from one location and placed in a different location within the same individual. Teeth can be transplanted from one place to another and a tooth or a root can also be transplanted to a more suitable position within the same socket.

Although replacement of lost or missing teeth in adults is nowadays more often carried out by implant treatment, there is a number of situations where autotransplantation seems to be a better alternative, especially in growing children and adolescents where implants cannot be used due to the interference with growth of the alveolar process.^{6,7,80,81} A transplanted tooth with PDL will follow and contribute to the development of the alveolar process and in many situations is therefore the first alternative for replacement in growing individuals. There are also situations in adult patients where autotransplantation is a possible alternative.^{3,6,22,30,31,33,35–37,44,59,61}

Donor teeth

Transplants can be taken by using teeth in crowded regions or by strategic extraction when equalizing the number of teeth between quadrants. Moreover, many premolars are extracted as part of the orthodontic treatment and can be used as transplants. Third molars can also be used (Fig. 17.1). The transplanted tooth must have a suitable root length and shape.^{3,6,54,57,58,61,68}

Teeth with roots under development are easier to extract and have better prognosis. Developing teeth can revascularize while fully developed teeth do not revascularize and have to be endodontically treated.^{3,6,7,76–78} It is also important to take into consideration the development and growth status of the individual and an interdisciplinary approach is important when planning.

Fig. 17.1 Transplantation of immature impacted third molar to the site of congenitally missing second premolar. (a) The patient is a 20-year-old male with a congenitally missing premolar 35 and a remaining deciduous molar 75. The root has been resorbed. (b) Radiograph showing resorption of 75. (c, d) Cone-beam CT images of the recipient site. The measurement of the recipient space has shown it is wide enough to accommodate the donor mesio-distally and bucco-lingually. (e, f) Cone-beam CT images of the donor tooth. The measurement has revealed the tooth is small enough to be placed into the recipient site. The lower left impacted third molar 38 is considered to be a good donor tooth for transplantation. (g, h) Extraction of the donor tooth 38. Note the Hertwig's epithelial sheath is preserved at each apex. (i) Extraction of the tooth from the recipient site. (j) After careful try-in of the donor into the recipient site, suturing of the flap is performed without placing it in the socket. A knot is tied on the buccal aspect of the interproximal area and about 3 cm of one of the sutures is left. Another interrupted suture is tied across the vertical releasing incision on the mesial aspect. Again, 3 cm of one end is left. Next a suture is placed through the interproximal area of the mesial aspect but in this procedure only one knot is tied loosely so that it allows space for the donor tooth to be placed into the socket. (k) Just after suture splinting. The loosely tied suture is tied tightly after placing the donor tooth. The tooth is tied into place by using a crisscross method. The remaining distal buccal end is tied with the mesio-lingual end and a knot is made on the center of the occlusal surface of the donor tooth. A horizontal mattress suture is tied on the disto-lingual aspect, and the remaining suture is tied to the remaining suture from the first crisscross knot. The remaining suture is then tied to the long remaining end of the suture from the vertical releasing portion. This allows the donor tooth to be seated in the correct position. Any excess suture is cut. (l) Occlusal adjustments are made on the antagonist so that articulating paper can freely slide through the contact. In this case, the opposing tooth was slightly extruded, so with the patient's permission, some adjustments were made to the opposing tooth in contact. (m) Radiograph immediately after transplantation. Note the apices are wide open. (n, o, p) Follow-up after 1 year, 8 months. The transplanted tooth has erupted and is in contact with the antagonist. Pulp healing and root development are seen.

Indications

Congenitally missing teeth

Tooth aplasia is a suitable indication for autotransplantation (Fig. 17.1). Donor teeth can be other erupted or impacted teeth or strategically extracted, e.g. taken from a crowded area or when a tooth does not have an antagonist. Another indication can also be to equalize teeth between quadrants. If the space is too small preoperative orthodontic widening may be necessary.^{3,82} An advantage with this type of transplantation is that a natural biological condition for bone and soft tissue development of the alveolar

process in the young growing patient is achieved and normal eruption is promoted.^{7,8}

Unrestorable teeth

Autotransplantation may be indicated in situations with deep caries or where restoration or crown therapy is not feasible or when endodontic treatment has failed (Fig. 17.2).

Crown-root and root fractures

Intra-alveolar transplantation,⁸³⁻⁸⁶ also called surgical extrusion,⁸⁷⁻⁸⁸ can be used to move a fractured

Fig. 17.2 Transplantation immature third molar 48 to replace an unrestorable first molar 46. (a) Occlusal view of the non-restorable 46. (b) Radiograph of 46. It was considered transplantation of an immature third molar would give a better prognosis than preserving 46 in this young patient. (c) 2 weeks after the extraction of 46. Transplantation was performed on the same day. (d) Extracted 48 as a donor. Note Hertwig's epithelial sheaths are preserved apically. (e, f) Immediately after transplantation. (g, h) 4 years' follow-up. The transplant shows a positive electric pulp test and normal healing is seen clinically and radiographically.

root to a more coronal position in the alveolar socket so crown therapy will be enabled. The root can be extracted either directly with forceps or via an open flap approach if the root is submerged. If the remaining root is long enough to carry a crown the root can be transplanted to a more suitable position in the socket. In some cases it may be suitable to rotate the root to 180°, to achieve a larger area of the root within the alveolar bone (Fig. 17.3). By doing this, the root is secured in its new position and does not slide back. Endodontic treatment should be performed within the first weeks after transplantation and crown therapy can usually be finished within 3 months after the transplantation. This method is a first choice of treatment in growing individuals where implant treatment is contraindicated, but can also be performed in adult patients as an alternative to implant treatment (Fig. 17.3).

Lost teeth in young growing patients

Incisors are sometimes lost because of tooth avulsion or cannot be restored after complex trauma. In adults such lost teeth are often replaced by implants; however when the patient is young and still growing implant treatment is contraindicated because implants will not follow the growth and development of the alveolar process. In such a case it can be difficult to achieve a good esthetic final result because the tissues do not develop normally in an esthetically sensitive area. Tooth transplant will enable continuing growth and development of the bone and soft tissues of the alveolar process during the time an individual is still growing and is therefore often a first choice when replacing teeth in young individuals who are still growing (Figs 17.4 and 17.5).

Lost teeth in adults

Teeth lost in individuals who have finished growing are usually replaced by implants. However autotransplantation can also be performed in adult

patients after tooth loss. However since these teeth have fully developed they will not revascularize and must therefore have root canal treatment.

Autotransplants vs implants

Since the introduction of implants many surgeons today prefer implants to replace lost teeth in *adult patients* who have finished growing. However, autotransplantation of teeth can also be performed in adult patients. Third molars may still be undergoing root development in young adults; these can be excellent transplants and revascularization can occur. Teeth with fully formed roots can be transplanted provided root canal treatment is performed. Implant treatment cannot be afforded by all patients and autotransplantation may be an alternative.

In *young growing patients* implant treatment is contraindicated in the anterior maxillary region because it stops the vertical growth of the alveolar process and it can be difficult to achieve a good esthetic final result if an implant is placed before growth is completed. To support the development of normal tissue in the trauma area and to secure growth and development of the alveolar process in an individual who is still growing, transplantation of the tooth is an excellent form of treatment (Figs 17.4, 17.5; see also Fig. 17.13).

Principles of healing after autotransplantation

Two tissues are of main importance for an autotransplantation to be successful, the pulp and the periodontal ligament. When a tooth is transplanted the vascular supply is immediately lost. Revascularization is therefore of utmost importance if the pulp is going to survive. Studies of transplanted teeth have shown that young teeth with ongoing root development and open apex can revascularize (Fig 17.6).^{72,74,76–78} Successful healing is related to the stage of root

Fig. 17.3 Crown-root fracture and surgical extrusion. (a, b, c) A 32-year-old female has sustained dental trauma in the anterior area. Three incisors have been injured. Both central incisors were subjected to lateral luxation with crown fracture and the right lateral incisor suffered crown-root fracture. In this presentation, the treatment is focused on the lateral incisor. (d) Removal of the coronal fragment of 12. (e) The extracted crown root fragment 12 before transplantation. (f) The transplanted 12 immediately after surgical extrusion. The tooth was rotated 180°, so that the palatal aspect is now facing buccally, and transplanted to an extruded position. A suture has been placed to hold the tooth in the correct position. (g) Radiograph immediately after surgical extrusion and rotation of root fragment through 180°. The endodontic treatment was performed before surgery and the canal was filled temporarily with radiopaque calcium hydroxide. (h) Cone-beam CT image immediately after surgery. (i) 5 weeks postoperative appearance just before the restoration of the crown with composite. (j) 4 years' follow-up. The crowns of the three traumatized incisors 12, 11, and 21 have been restored with composite. (k) 4 years' radiographic follow-up. Normal healing is seen. (l) Cone-beam CT image of tooth 12 at 4 years' follow-up. Normal PDL space along the root surface is observed and the thin buccal bone plate is preserved.

development (Fig. 17.7).³ In order to optimize conditions for revascularization, transplantation should ideally be carried out before the root reaches full root length and when the root apex is still open (Figs 17.7, 17.8). However, the transplantation cannot be performed at too early a stage of root development since there is a risk of arrested root development after transplantation (Fig. 17.9). Teeth with fully developed roots and a closed apex cannot be expected to revascularize but can still be transplanted provided root canal treatment is performed.

Pulp

Immature roots (open apex)

In the first weeks after transplantation before the pulp has regained its vascularization, the tissue is very

prone to infection. If the pulp is infected the transplanted tooth can be destroyed by inflammatory root resorption. Experimental studies have shown that systemic antibiotics can reduce this risk and for this reason systemic antibiotic administration is routine during the first week after transplantation.⁷ Routes of infection to the non-revascularized pulp must be avoided, so grinding on the transplant should be avoided since this may open up communication routes for bacteria through the dentinal tubules to the pulp. If these principles are followed infection of the non-vascularized transplant is very rare, and after a few weeks revascularization has taken place. Because of the temporary interruption of vascular supply, later calcification or obliteration of the pulp is seen (Figs 17.4–17.6).^{3,6,7} This is a normal finding in a tissue that has had an interrupted vascular supply and this condition requires no treatment. The condition should

Fig. 17.4 Autotransplantation of mandibular premolar to the central incisor area with a closed technique. (a) Transplanted premolar sutured into position. The postoperative immediate radiograph shows incomplete root development. (b). Follow-up nine years after transplantation. The crown has been built up by composite. Radiograph shows that full root development has been achieved and the usual obliteration is seen indicating the pulp has survived. (From Andreasen, Andersson, and Tsukiboshi.⁷ Reproduced with permission from Wiley-Blackwell.)

Fig. 17.5 (a, b) Autotransplanted premolars. (c) The transplants were later restored with porcelain laminate veneers. (d) Radiograph after restoration. (From Andreasen, Andersson, and Tsukiboshi.⁷ Reproduced with permission from Wiley-Blackwell.)

Fig. 17.6 Schematic illustration of pulp healing and root development after transplantation of an immature (open apex) tooth. (a) Before transplantation: an immature tooth, with Hertwig's epithelial root sheath attached to the apex, is transplanted into the recipient site. (b) Several days after transplantation: capillary vessels proliferate coronally from the apical foramen and pulp cells proliferate along with them and the pulp canal is filled with vital tissue during the first weeks after transplantation. (c) Several months later: rapid calcification of the root space occurs resulting in a partial obliteration. At the same time Hertwig's epithelial root sheath may allow for some root development to take place.

rather be seen as a sign that the pulp has survived the transplantation trauma, since it had a capacity to form hard tissue after it had been transplanted.

Mature roots with closed apices

Transplanted teeth with fully formed roots and closed apices will not revascularize and must always have root canal treatment to avoid later infection and inflammatory root resorption.

Periodontal ligament

It is very important for the prognosis of the transplanted tooth to minimize damage to the PDL. It can be damaged in different phases of the transplantation

procedure: when the transplant is mobilized from its original position, when it is stored outside the mouth, and when it is placed in its new position. Small areas of damage to the root surface can heal by proliferation of cells from the side of the defect, however if a larger area of cell damage has occurred during the transplantation procedure, the remaining PDL cannot proliferate and bridge over the defect with new PDL.⁷⁰ Instead there is risk for bone overgrowth from the alveolar socket so the tooth becomes fused with the alveolar bone.⁶⁹ This will result in ankylosis and replacement resorption and the transplant will be replaced by bone and finally lost. To avoid damage and root resorption careful surgical technique is of utmost importance. A higher risk for replacement resorption is seen in transplantation of teeth with

Fig. 17.7 Relation between root length and pulp healing. Stages of root development of donor teeth, modified after Andreasen.³ The solid line represents expected root completion after transplantation. The dotted line represents the probability of revascularization and pulp healing. The dashed line represents periodontal ligament healing. After closure of apex, the chance for revascularization and healing of the dental pulp decreases. Conversely, as there is less root development, the healing of dental pulp increases. For there to be an ideal point where there are both maximized root completion (final root length), periodontal and pulp healing, the autotransplant should be performed when the donor tooth is at stage 4 to 5 of tooth development (i.e. when the root is 70–80% developed).

Fig. 17.8 Transplanted molar with optimal root length. The patient is a 17-year-old female. (a) Immediately after transplantation. (b) 8 months later. The root of the transplant is developing. (c) 6 years later. The root development is completed to full root length.

Fig. 17.9 Total arrest of root development after transplantation carried out too early before root development was optimal. The patient is a 16-year-old male. (a) Immediately after transplantation. The upper right third molar is transplanted. (b) 4 months later: Pulp healing is observed but little or no root development is seen. (c) 1 year later: The root development of the donor is almost totally arrested.

Fig. 17.10 Principle of healing after placement of transplant in a socket which is wider and deeper than the transplant. (a) Before transplantation. The donor tooth 48 with intact PDL is placed in the surgically and newly formed socket 46. Healing of the PDL is dependent on the viable PDL of the donor tooth. (b) Just after transplantation. The PDL which is present above the crestal bone level allows for reattachment to the gingival connective tissue. A blood clot forms between the bony socket wall and the rest of the root. (c) After completion of healing. The blood clot is replaced by granulation tissue and immature bone in 1–3 weeks and mature bone is in place after about 1–6 months, depending on the width of the space and the age of the patient.

Fig. 17.11 Case illustrating bone healing capacity of PDL after transplantation. (a) Before transplantation. Tooth 36 is going to be replaced by 38, which is not in occlusion and lacks an antagonist. (b) Just after transplantation. Note the wide space between the donor and the socket walls. (c) 2 years postoperatively. New bone has been formed and a normal PDL space is seen around the transplanted tooth.

fully developed roots, probably because these teeth are more difficult to manage without damaging the PDL.³ If there is a chance of choosing a transplant with a root under development the prognosis is better. Short-term fixation and some mobility during the healing period will promote healing with periodontal ligament.^{91,92} For this reason transplants should not be rigidly splinted and can be held in place by sutures or a flexible splint instead of rigid splints. The PDL of the transplant also has an osteogenic regenerative capacity and bone will be formed around the transplant provided the PDL is not severely damaged

even if the transplanted tooth is placed without bone contact (Figs 17.10–17.13).^{3,6,7}

Principles of surgery

Possible transplants can be strategically extracted teeth, e.g. premolars from areas with crowded teeth or areas where the number of teeth in a quadrant is going to be reduced and equalized to an adjacent quadrant. The treatment should therefore ideally be planned together with an orthodontist who can

Fig. 17.12 Case illustrating bone healing capacity of the PDL after transplantation. The patient is a 15-year-old female. (a) Just after transplantation. The tilted and ectopically erupted upper right second premolar has been transplanted on the aplasia site 45. (b) 3 months postoperatively and just after the root canal treatment. The necrotic pulp was removed and calcium hydroxide preparation was placed for apexification. Note that new bone has started to form around the transplant. (c) 1 year, 5 months postoperatively. Normal healing with complete bone regeneration.

advise on a suitable transplant and perform preoperative and postoperative orthodontic treatment when required. It is important to have a thorough preoperative radiographic examination with panoramic radiographs and periapical dental films of both the donor and recipient areas to estimate root anatomy, root development, and space conditions. Cone-beam computed tomography (CT) is a helpful preoperative tool (Figs 17.1 and 17.13). Other important structures such as the mandibular canal, mental foramen, and maxillary sinus must also be taken into consideration. The available space in the recipient area is measured with cone-beam CT but a sliding caliper and study casts are also helpful if the donor tooth is erupted. A simple conical root anatomy of the transplant is ideal. A position in the jaw enabling a non-complicated removal is especially valuable for the prognosis. Transplants in complicated positions must be avoided since removal will often result in damage to the PDL. Estimation of the degree of root development is the key factor in order to time the transplantation. A root development of 70–80% seems to be optimal (Fig. 17.7).

Surgical techniques

A prerequisite for a successful result of transplantation is that the capacity of the tissues for healing and regeneration is preserved. For this reason there are special requirements regarding the surgical techniques. It is important that the surgeon has a full understanding of the highly sensitive tissues involved. At the moment of extraction of the transplant, the pulpal tissue in the transplant is losing its vascular supply and must later be revascularized. In order to protect the pulp from infection, systemic antibiotics are given 1 hour before surgery so there is a high concentration of antibiotics in the pulp tissue. The surgical trauma must be minimized so that the transplant and the tissues of the recipient region are not damaged; this means that the recipient area must first be prepared before moving of the transplant. After careful raising of the flap the alveolus is prepared under intense cooling with saline. For this reason measurement of the donor tooth should be performed preoperatively on radiographs and clinically if the

transplanted tooth is erupted. In many cases the alveolar bone is completely removed which does not seem to have any negative effect on the PDL as long as the PDL of the transplant is intact.^{3,6,7} An intact PDL has an ability to form new periodontal tissue including new bone (Figs 17.10–17.13). Soft tissue in the recipient region should be protected during the preparation. The next moment is exposure and loosening of the transplant. An unerupted tooth germ can usually be lifted out with its intact follicle and root sheath. In ideal situations the transplant can be moved directly over to the recipient site. However, adjustments are often needed and the extra-alveolar time should be kept as short as possible. The transplant can be stored in physiologic saline if preparation of the recipient site is required. A sliding caliper or probe can be used for measurement. Plastic or metal dummies or even earlier extracted autoclaved premolars can be used as try-in dummies. Changing the direction of the tooth by rotating it 90° can help to find a better fit. Grinding on the transplant should be avoided. Grinding of the enamel of the adjacent teeth may be necessary but the space should ideally have been prepared before surgery by orthodontic treatment. The graft should ideally be placed somewhat below the occlusal plane and placed passively into its new position without any pressure from the adjacent tissue. The flap is replaced, covering the transplant without pulling too hard on the tissue, and the transplant is secured with a suture over the occlusal surface or with a flexible splint (Fig. 17.1).

Postoperative care

The patient should have systemic antibiotics and should be recommended a soft or liquid diet and rinsing with chlorhexidine during the first week. After 1 week the sutures can be removed and after 4 weeks the transplant will have achieved almost normal mobility. During the first year, eruption and continuing root development with obliteration of the root canal are signs of successful transplantation with revascularization and pulp survival. Teeth with fully formed roots should be root canal treated and this should be initiated 2 weeks after transplantation.

Long-term prognosis

There are some studies reporting tooth survival after tooth transplantation in almost 100% of cases. However, evaluating with more strict criteria, i.e. not only survival but healing without any signs of progressive root resorption during an observation time

of several years, achieves a more relevant success rate. Using such evaluation criteria the success for a transplanted molar is 72–90%, for premolars is 89–98%, and for canines is 25–81%.³ The higher success figures are for studies with teeth with developing roots with open apices and revascularization. Transplanting teeth with fully developed roots has a

Fig. 17.13 Transplantation with sinus elevation. (a) Panoramic views of 21-year-old male at the first examination. He had an infection in an earlier endodontically treated tooth 26. Tooth 28 is a potential donor tooth. (b) Clinical picture showing deep palatal crown–root cusp fracture. (c) Cone-beam CT facial image around the recipient site. There is apical periodontitis which has caused the breakdown of the sinus floor around the mesio-buccal root. In addition, the sinus floor is located inferior to the root apex. The vertical bone height is 5 mm. (d) Cone-beam CT sagittal image of the donor tooth verifying its suitability as a donor tooth with conical root shape and open apex (stage 5, Fig. 17.7) with a diameter wider than 1 mm which means there is a chance for pulp revascularization after transplantation. (e) Cone-beam CT coronal image of the recipient. The second canal of the bucco-mesial root of 26 has been untreated and caused the apical inflammation. (f) Radiograph taken 2 weeks after extraction of 26 and just before transplantation. (g) The extracted donor tooth 28, an open apex with Hertwig's epithelial sheath is observed. (h) Radiograph immediately after transplantation. Note the sinus has been elevated to enlarge the vertical space to accommodate the donor. (i) Clinical view immediately after transplantation. (j) Cone-beam CT images 3 days after the surgery. There is a wide bony space around the transplant. (k, l) 5 months' follow-up. Bone has formed and the transplant showed positive sensibility. (m, n) 3 year, 5 months' follow-up. PDL healing, normal pulp and bone healing. (*cont'd*)

Fig. 17.13 (cont'd) (o) Cone-beam CT images at 3 years, 5 months' follow-up showing successful bone regeneration and healing.

lower success rate due to a higher risk for damage of the PDL with resulting root resorption. There have been studies trying to improve the prognosis in auto-transplanted teeth with fully developed roots by using a two-stage technique.^{35,42,43,77} For intra-alveolar transplantation (surgical extrusion) a success rate of 88–90% has been reported.^{83–89} Numerous clinical and experimental studies of autotransplantation and replantation have resulted in today's understanding of the healing process and how to avoid or reduce the risk of complications after autotransplantation.^{3,5,6,7,53–58,60,63–65,67–71,74–80,90–94}

Summary

Transplantation of teeth is a well documented treatment method that should always be taken into consideration as a first treatment alternative in young growing patients with congenitally missing teeth and in situations of tooth loss after trauma in growing patients. A transplanted tooth can contribute to normal development of the alveolar process when the patient is still growing. In adult patients there are also certain situations where autotransplantation can be a preferable alternative to other treatments.

Chapter 18

Endodontic Surgery

Peter Carrotte and Colin Murray

Periradicular surgical procedures are carried out to treat diseases and conditions of the tooth root that are not amenable to orthograde root canal treatment. The majority of these surgical procedures will involve resection of the root apex (apicectomy) and retrograde obturation of the root canal to address persistent disease that has not resolved following an acceptable root canal treatment. Other surgical procedures on the tooth root, including the repair of resorption defects and root perforations, will also be considered in this chapter. Great emphasis has been placed on describing modern microsurgical techniques and instrumentation, and a comprehensive literature review is included to support this move away from a more conventional surgical approach. These microsurgical techniques appear to result in improved prognosis, with better and more esthetic healing of the alveolar and gingival tissues. This is of considerable importance in today's climate of esthetic dentistry and patient expectations.

Introduction

Periradicular surgery procedures

Periradicular surgery (PRS) is a generic term for treatment that encompasses three main categories of surgical endodontic procedures:

1. Periapical curettage of persistent periradicular disease, including removal of the root apex (root-end resection) and retrograde filling of the root canal.
2. Surgical repair of root surface irregularities such as external root resorption defects or iatrogenic perforations.
3. Root resection of posterior teeth to remove diseased roots and retention of roots suitable for further coronal restoration.

The majority of PRS procedures are related to the first of the above categories. This is a procedure often referred to as an apicectomy (or apicoectomy) and will be discussed first in this chapter. The latter two surgical endodontic groupings will be discussed towards the end of the chapter. However, the primary objective of all these surgical therapies is to repair any underlying defect thereby facilitating regeneration of local dentoalveolar tissues.

Box 1 Abbreviations used in this chapter

CAD/CAM	Computer-aided design/computer-aided manufacturing
CBCT	Cone-beam computed tomography
EDTA	Ethylene diamene tetra-acetic acid
GTR	Guided tissue regeneration
MTA	Mineral trioxide aggregate
NSAIDs	Non-steroidal anti-inflammatory drugs
NSRCT	Non-surgical root canal treatment
PRD	Periradicular disease
PRS	Periradicular surgery
SEM	Scanning electron microscopy
SOM	Surgical operating microscope

Historical perspective of surgical endodontics

The first published description of a periradicular surgical procedure found by the authors was in 1890. Using examples of his own clinical cases as illustration, Dr Rhein¹ began by suggesting that *“although amputation of a portion or the whole of the root for the restoration of health of teeth which did not yield to milder treatment had long been advocated by the few, the textbooks were singularly quiet about this important procedure”*. He proceeded to describe the technique known today as “through-and-through” apicectomy as follows. *“Usually the operation presented no difficulty and, except in the region of the antrum or mental foramen, no dangerous anatomical points were involved. The instruments required were a sharp spear-shaped drill to open through the process and root, and a new fissure-bur, which, following the drill and worked laterally, severs the root. As a rule, no anaesthetic was required...”* The method of treatment which the writer advised was *“To fill the root or roots, excise the diseased portion, following with a vigorous use of the bur in the surrounding pathological tissue. If the operation were performed under aseptic conditions and the parts kept so until the wound was entirely healed, an immediate and radical cure resulted.”* The first published description of an apicectomy coupled with a retrograde cavity and restoration of the root apex found by the authors was in 1916. Using excellent clinical photographs, Carl Lucas² described a procedure which bears remarkable similarities to the conventional surgical techniques advocated until quite recently, before today’s oral surgeons recognized the importance of, and adopted, microsurgical techniques described in this chapter. Lucas even appears to have used the “Ochsenbein-Luebke flap” which would not be described in the literature for another 10 years.³

Initial clinical assessment

Prior to embarking upon any PRS procedure, the operator must undertake a comprehensive medical and dental assessment combined with a thorough extra- and intraoral examination. The overall condition of the mouth, including both the soft tissues and dentition, needs to be assessed. In particular, the presence of local infection, swelling and sinus tracts should be recorded. The caries status of teeth should be evaluated and the presence of and quality of the coronal restoration on the tooth requiring surgery should be carefully considered. If the tooth is restored with an indirect restoration, the patient should be asked if it has ever become decemented or debonded. The periodontal status of the tooth, in addition to the rest of the dentition, requires careful evaluation with appropriate periodontal probes for assessing the presence of isolated deep pockets and analysis of tooth mobility. The occlusal function of the tooth should be noted and it should be ascertained if the

tooth is a functioning unit. Radiographic assessment is covered later in this chapter.

Why periapical surgery?

An apicectomy is indicated when conventional non-surgical root canal treatment (NSRCT), with an orthograde root canal filling, has failed or is impractical and the tooth is associated with clinical symptoms or signs of continuing periradicular disease (PRD). It must be emphasized at the outset that a surgical approach is not a substitute for providing satisfactory orthograde root canal treatment. If orthograde treatment has failed, the reason for failure should be diagnosed and, whenever possible, NSRCT retreatment attempted. Therefore, surgical root canal procedures should not be considered as the primary treatment option to treat teeth with associated apical pathology.⁴

The radiographs in Figs 18.1 and 18.2 depict two such cases. An inadequate root canal treatment that has failed is illustrated in Fig. 18.1. A periapical radiolucency persists, which was associated clinically with a draining sinus. The reason for failure is inadequate preparation and disinfection of the root canal system. Before even considering a surgical approach, such a case should be endodontically treated by orthograde retreatment to the accepted standard. A root canal treatment that has failed because an endodontic instrument has separated in the root canal preventing radicular access for disinfection and obturation is presented in Fig. 18.2. If it is not possible to remove the separated instrument and undertake orthograde retreatment, a surgical procedure may be necessary. Surgery has been demonstrated to be more commonly performed if there are persisting symptoms and/or progression of the periradicular lesion and in teeth restored with post and core crowns.⁵ Before proceed-

Fig. 18.1 A radiograph showing an inadequate root canal treatment that has failed. A periapical radiolucency persists, which was associated clinically with a draining sinus. The reason for failure is inadequate preparation and disinfection of the root canal system. Before even considering a surgical approach, such a case should be endodontically treated by orthograde retreatment to the accepted standard.

ing, it may therefore be helpful to briefly review current guidelines for achieving satisfactory orthograde root canal treatment.

Root canal infections

Kakehashi and co-workers⁶ demonstrated more than 40 years ago that pulpal and subsequent periradicular disease is caused by microbial contamination. This commonly occurs via a carious lesion. As resultant necrosis of the pulpal tissue proceeds, initially inflammatory products and later pathogens and their by-products exit the confines of the root canal system through the apical foramen. Unless there is a dysregulated acute inflammatory reaction resulting in an apical abscess, chronic periapical periodontitis develops. This frequently results in the formation of a PRD lesion, most commonly an apical granuloma (Fig. 18.3). This chronic inflammatory tissue response comprises granulation tissue, containing fibroblasts, epithelial cells, lymphocytes, neutrophils, plasma cells, mast cells, and macrophages, and directly contributes to destruction of the surrounding dentoalveolar bone.

An effective immune response leading to resolution of PRD is not possible as the source of infection, contained within the root canal space, is inaccessible to mediators of host immunity. Therefore, the pathological apical lesion will only resolve when the origin of infection is eradicated, the root canal system effectively sealed, and a satisfactory coronal restoration placed. An effective three-dimensional seal is prerequisite to successful outcome. As it is never possible to completely sterilize the root canal system, an apical seal will prevent egress of any remaining toxins into the surrounding periradicular tissues. Furthermore, an effective coronal seal is essential to prevent re-entry of microorganisms from the oral cavity into the root canal.

Fig. 18.2 A radiograph showing an attempt at a root canal treatment that has been referred for specialist treatment because an endodontic instrument has separated in the root canal preventing radicular access for disinfection and obturation. If it is not possible to remove the separated instrument and undertake orthograde retreatment, a surgical procedure may be necessary.

Orthograde root canal treatment

NSRCT is performed using endodontic files and other instruments to shape the canal sufficiently in order to permit the ingress of antibacterial medicaments to the entire root canal system. The antiseptic irrigant of choice is a solution of sodium hypochlorite, the concentration of which is between 1% and 5% depending upon the operator's preference. In conjunction with this, a solution to disperse the smear layer formed on the root canal wall during instrumentation should be used; 17% EDTA (ethylene diamene tetra-acetic acid), which will disrupt the bacterial biofilm and smear layer, is preferred for this purpose but citric acid is also suitable. Other antibacterial solutions have been advocated for disinfection of the root canal system including 0.2–2% chlorhexidine gluconate and iodine–potassium–iodide. However, these lack the tissue dissolution properties of sodium hypochlorite and are not recommended as the sole irrigant for *de novo* treatment.

If the root canal space is inadequately prepared and shaped, the disinfecting irrigant solutions will not reach the apical extremity of the canal and infection will likely persist. Fig. 18.4 shows an example of failed root canal treatment due to inadequate shaping of the apical part of the root canals. If PRS was undertaken in such a situation, the reservoir of infected material remaining within the root canal system would significantly reduce the prognosis.

Non-surgical root canal treatment outcomes

Many clinical studies report high success rates for NSRCT of greater than 90%.^{7,8} Conversely, others have reported the success of NSRCT to be as low as 45%.⁹ Epidemiologic studies consistently report significantly lower rates of NSRCT success than

Fig. 18.3 An apical granuloma attached to the root apex. The chronic inflammatory response comprises granulation tissue containing fibroblasts, epithelial cells, lymphocytes, neutrophils, plasma cells, mast cells, and macrophages and directly contributes towards destruction of the surrounding dentoalveolar bone.

Fig. 18.4 A radiograph showing a failed root canal treatment due to inadequate shaping of the apical part of the root canals. If PRS was undertaken in such a situation, the reservoir of infected material remaining within the root canal system would significantly reduce the prognosis.

endodontic treatment undertaken within controlled clinical settings.¹⁰ Indeed, the majority of investigations reporting high success rates in the treatment of PRD are limited to procedures undertaken upon selected cases treated by endodontic specialists or supervised trainees.¹¹ Nevertheless, Cheung¹² ascertained that success rates of root canal treatment in patients receiving treatment within training institutions can be as low as 50%.

Studies analysing cross-sections of the general population identify that the technical quality of NSRCT is performed to a satisfactory standard in only 30–42% of cases.¹³ It appears that root filled teeth are 5–12 times more likely to have radiographic evidence of PRD than teeth without root fillings.^{13,14} Furthermore, teeth with inadequate root fillings demonstrate a significant correlation with the presence of PRD.¹⁵ Part of the reason for treatment failure with root canal fillings may be attributed to the lack of effective intracanal medicaments that eliminate a broad spectrum of microorganisms during cleansing of the root canal. A recent meta-analysis of published root canal treatment literature calculated the success rate for root canal treatment to be 82.8% for vital teeth and 78.9% for non-vital teeth. This provides a cumulative success rate of 82% for teeth without evidence of PRD and 71.5% for teeth with a periradicular lesion.¹⁶

Periradicular disease lesions and outcomes

Associations have been made between failed root canal treatment and missing adjacent teeth, greater plaque accumulation, the degree of marginal bone support, a history of trauma to the treated tooth, the lack of postoperative coronal restoration, and older patients.^{17,18,19} Importantly, current evidence clearly identifies that the most significant factor influencing the successful outcome of NSRCT is the presence and magnitude of a PRD lesion prior to commencing treatment.^{16,20,21}

In addition to localized tissue destruction, it is suggested that chronic persistence of PRD may have an effect upon the host's systemic inflammatory mediators.²² Indeed, a reduction in peripheral blood levels of acute-phase proteins compared to controls has been demonstrated after completion of endodontic treatment.²³ However, it is only gradually being recognized and accepted that the host's immune response is an important factor in the outcome of endodontic treatment, this having previously been largely ignored.²⁰

Microflora of the PRD lesion

There is controversy as to whether the PRD lesion *per se* is sterile or whether microorganisms invade and inhabit the inflamed tissue.²³ Early studies provided evidence that PRD lesions contained significant numbers of bacteria.^{24,25} Nonetheless, others^{26,27} were not able to corroborate these findings. Recent investigations^{28,29} have reinforced the conjecture that PRD tissue contains bacteria. Moreover, when using conventional culture techniques, these bacteria are established as being viable.^{30,31} Indeed, it has been demonstrated that as many as 90% of PRD lesions contain cultivable bacteria.³² Nevertheless, microbes are frequently found in only very small numbers within the lesion.³³ Furthermore, only a small percentage of PRD tissue has been shown to contain bacteria within the body of the lesion.²³ It therefore remains controversial as to whether the majority of these microorganisms are contaminants arising during surgical removal of lesions. The possible contribution of these extraradicular microbes towards the perpetuation of PRD therefore remains to be elucidated.

Apicectomy procedures

Historically, the operation of "apicectomy" has frequently been performed without due regard to these aforementioned endodontic concerns thereby resulting in literature reports of a poor prognosis from such surgical procedures. In 1970, Harty *et al.*³⁴ published a report of 1016 periradicular surgery cases claiming a success rate of 90%. However, almost 30% of their

cases did not return for recall. Indeed, two other papers published during that time, using amalgam retrograde fillings, established prognoses following apicectomy procedures of only 59–70%. In 1992, Frank *et al.*³⁵ observed that in cases where amalgam had been used as the retrograde filling material the success rate was less than 56%. The concluding sentence in their paper reads, “It is our hope that this report will be an impetus for further investigations on materials and methods to replace apically placed amalgam fillings to give improved long-term results.”

It is therefore essential to note that recent reports of outcomes from PRS procedures using modern techniques and materials outlined in this chapter have been much more favorable. When using magnification and ultrasonic root-end preparation, Taschiere *et al.*³⁶ recorded successful outcomes in over 92% of their PRS cases. Tsesis *et al.*³⁷ presented a comprehensive review of the literature of prognosis of traditional and modern techniques. Employing current surgical techniques described in this chapter, they observed complete healing in 91% of cases. This is in comparison to successful outcome in only 44% of cases where traditional surgical methods were used for PRS. Before embarking upon PRS, the clinician must therefore be fully conversant with current orthograde endodontic teaching and practice. Thereby, cases that are more suited to NSRCT retreatment will be directed accordingly towards such treatment modalities rather than PRS approaches.

Therefore, in teeth with failing root canal treatment and persisting periradicular lesions, NSRCT retreatment is generally regarded as the treatment of choice as this has a higher success rate than surgical procedures.³⁸ Nevertheless, in certain clinical situations root canal retreatment may not be feasible. Teeth restored with large post-core crowns may suffer root fracture on attempting post removal and some teeth may have inaccessible canals. According to the Royal College of Surgeons of England guidelines, periradicular surgery may therefore be the preferred treatment option in these cases.³⁹ Indications and contraindications for undertaking PRS are outlined in Table 18.1.⁴⁰ It is evident that many patients referred by general

dentists for PRS actually require NSRCT retreatment.⁴¹ It is therefore important that the surgeon has a good liaison with endodontic colleagues for the appropriate management of such cases.

The surgical procedure aims to remove the necrotic and infected dental root apex, curettage and remove the periradicular lesion, and seal off the apical aspect of the root canal. Indeed, the apical seal of the root canal with a retrograde root filling has been demonstrated to be a major factor towards the successful outcome of PRS.^{34,42} There have been several significant advances in endodontic surgical procedures over the past decade. These include the development of improved root-end filling materials such as mineral trioxide aggregate (MTA),^{43,44} the introduction of magnification,⁴⁵ and the use of ultrasonics in root-end preparation.^{36,46} We discuss each of these in turn in this chapter.

Local anatomic considerations

General principles in the handling, management, and healing of the soft tissues of the oral cavity, both alveolar mucosa and attached gingiva, are discussed elsewhere in this textbook. However, before embarking upon PRS some fundamental observations on the hard tissues, both bone and teeth, are of particular relevance to PRS treatments.

Mandible

When carrying out PRS in the mandible, consideration must be given to the path of the inferior dental nerve bundle in the mandibular canal, which lies in close proximity to the root apices. Surgeons must also be aware of the position of the mental nerve exiting through the mental foramen, which lies between the apices of the lower premolars. If a vertical relieving incision is required when gaining access to posterior mandibular teeth, it should be made over the mandibular canine, having carefully palpated the mental foramen. If a more distal incision is prescribed for PRS to the molar teeth, then care must be taken to avoid the facial artery as it crosses the border of the

Table 18.1 Indications and contraindications for surgical endodontics. (Adapted from ESE guidelines 2006.⁴⁰)

Indications for surgical endodontics	Contraindications for surgical endodontics
Radiological findings of periradicular periodontitis and/or symptoms associated with a canal where an obstruction cannot be removed or will result in damage	Local anatomic factors, such as an inaccessible root end
Extruded material with clinical or radiological findings of apical periodontitis and/or symptoms over a prolonged period	Tooth with inadequate periodontal support
Persisting or emerging disease following root canal treatment where retreatment is inappropriate	Uncooperative patient
Perforation of the root or pulp chamber floor which cannot be treated from within the pulp cavity	Patients with a severely compromised medical history
Biopsy of persisting periradicular lesion is required	Tooth is unrestorable
If patient considerations preclude prolonged non-surgical root canal retreatment	Inexperienced operator with no training

Fig. 18.5 The root apex frequently possesses multiple portals of exit. (SEM illustrations courtesy of Professor Benjamin Briseño.)

mandible adjacent to the first molar. The further posterior the tooth, the denser the overlying bone will be and the neurovascular bundle will be closer to the root apices. Access to second mandibular molars may be so difficult as to preclude surgery. A degree of difficulty may also be experienced when attempting to access lower incisor roots. A shallow sulcus, especially when coupled with a prominent mandibular protuberance, together with the lingual inclination of the roots may make access to the root apices extremely difficult. As 40% of lower incisors have two root canals, these difficulties may preclude adequate resection and retrograde filling of the root apex which may ultimately lead to treatment failure.

Maxilla

The principle anatomic consideration when performing PRS in the maxilla relates to the maxillary sinus. As the floor of the sinus may be only 1 or 2 mm above the root apices of the posterior dentition, the risk of perforation when disease is present is relatively high. Should preoperative assessment suggest that exposure of the sinus during surgery is a possibility then incisions should be designed to ensure that the operation site can be completely closed with a mucoperiosteal flap. Considerable care must be taken to prevent debris from entering the sinus during the procedure and, if adhered to, postoperative sinus-related problems may be avoided.⁴⁷

The other anatomic consideration in the maxilla relates to the position of the palatal root apices. It may be impossible to access these from a buccal approach, thereby necessitating a palatal flap. However, the greater palatine artery may restrict the size of flap raised and access can be difficult. Furthermore, replacement of palatal flaps can be challenging due to the concave shape of the palate and the potential for blood pooling beneath the flap. A surgical stent for postoperative use may be prepared in advance should such problems be anticipated.

Root and root canal morphology

A good knowledge of dental anatomy is essential to ensure that apical root resection is effective. The shape of individual roots varies as does the number

of root canals. Indeed, it is now accepted that root canal systems have much greater complexity at the level of root resection than previously recognized.⁴⁸ Furthermore, the root apex frequently possesses multiple portals of exit (Fig. 18.5). West⁴⁹ demonstrated that 100% of failed root canal specimens had unfilled or underfilled portals of exit at the apical area. Therefore, at least 3 mm of the root apex should be removed to ensure the best possible chance of successful retrograde obturation of all portals of exit. The angle of resection should be as close to horizontal as possible (see “Root-end resection” on page 303). The serious flaw in the traditional method of root resection at an angle of 45° can be seen in Fig. 18.6.

Preoperative imaging

Maxillofacial imaging is covered elsewhere in the textbook. However, certain aspects are of fundamental importance to undertaking PRS procedures. Conventional radiology has been the principle technique for assessing periradicular anatomy prior to performing endodontic surgery. This facilitates the assessment of the number, length and shape of the roots, the presence of a sclerosed canal, and type of

Fig. 18.6 The apex of the tooth on the left has been sectioned at 45° to the long axis. The serious flaw in the traditional method of root resection at an angle of 45° can be seen by the increased amount of infected root canal exposed compared to resection at 90° (right).

Fig. 18.7 A surgical operating microscope (SOM) in use during routine root canal treatment.

restoration present. However, these two-dimensional (2D) images of three-dimensional (3D) structures have their limitations. For example, conventional periapical radiographs do not facilitate accurate predictions in the preoperative assessment for the potential perforation of the maxillary sinus.⁵⁰

As a consequence, the use of 3D cone-beam computed tomography (CBCT) imaging is now becoming

established in preoperative assessment for PRS. The detail provided by 3D CBCT imaging in diagnosing the precise size and location of resorption defects⁵¹ or periradicular pathology^{52,53} is greatly beneficial over conventional radiography. Such enhanced pre-operative information allows improved precision in performing PRS procedures, thereby preventing complications arising through trauma to adjacent anatomic structures.⁵⁴ There is also emerging evidence that CAD/CAM guidance using CBCT imaging is capable of delivering more accuracy and consistency when undertaking endodontic surgical techniques.⁵⁵

Equipment and materials

Magnification

The modern approach to PRS is through magnification, illumination, and microsurgery. As referred to earlier, the dental literature is now reporting greatly improved prognosis when these techniques are employed.⁵⁶ Surgeons who have developed their skills in this field would not return to traditional PRS procedures. Although loupes are helpful, the improved illumination and magnification make the use of the surgical operating microscope (SOM, Fig. 18.7) essential for PRS.⁵⁷ A typical microsurgical instrument set-up is demonstrated in Fig. 18.8. Individual microsurgical instruments in comparison to their normal counterparts are presented in Figs 18.9–18.11. In addition to the SOM, endoscopy is being employed as a supplementary aid to further enhance magnification during PRS.⁵⁸

Along with greatly improved vision and illumination, microsurgery has many other benefits. The operator's posture is fixed comfortably in relation to

Fig. 18.8 A typical microsurgical instrument set-up for undertaking periradicular surgery.

the microscopic eyepiece. A correct upright posture is maintained, thereby reducing operator fatigue and strain. Far more detailed examination of the root apex is possible, allowing anatomic features such as isthmuses, accessory canals, fracture cracks, and crazing

Fig. 18.9 Comparison of microsurgeal mirrors to facilitate visualization of the root canal anatomy with a conventional dental mirror (left).

Fig. 18.10 Comparison of microsurgeal blades with conventional surgical blade.

to be identified. Angled ultrasonic instruments can be used to prepare the retrograde cavity with the aid of micromirrors. This allows visualization of the whole root apex in order to check that all infected debris and old root canal obturation materials have been removed. If failure to shape, clean, and fill the root canal system is acknowledged as the main reason for failure of *de novo* orthograde root canal treatment, exactly the same concerns apply to the surgical approach.

Root-end filling materials

As well as developments in microsurgery techniques, significant advances have been made in root-end filling materials. First described by Torabinejad *et al.* in 1995,⁴³ MTA (Fig. 18.12) is now recognized to have significantly better properties than any other material for this purpose. Unlike all of the other traditionally used root-end filling materials (amalgam, zinc oxide-eugenol cements, glass ionomer cements) the set of the freshly placed material is not affected by the presence of moisture, including blood. It is less cytotoxic and more tissue compatible than previously used materials. Reports from animal studies demonstrate less inflammation and greater cementum deposition over set MTA compared with other materials within days of surgery. Furthermore, scanning electron microscopy (SEM) images reveal cementoblasts adhering to the material. The only reported disadvantage of MTA is the slight difficulty in handling and placement. This has been overcome to a certain extent with the introduction of a white MTA material which in some respects has superseded the original gray powder. When properly mixed, it has a creamy consistency and is less difficult to place when using appropriate instruments.

Local anesthesia, medication, and hemostasis

The choice of local anesthetic agent for periradicular surgery is related to three distinct surgical requirements: anesthesia during the surgical procedure, hemostasis, and postoperative pain control. Clinical trials have not been able to elucidate any significant clinical differences between the various anesthetic agents currently available for dental use. However,

Fig 18.11 Microsurgical suture forceps and 5/0 suture in comparison to standard suture forceps and 4/0 suture (left). Microsurgical suturing with papillae preservation (right).

Fig. 18.12 Mineral trioxide aggregate (MTA) is available in three presentations: ProRoot original gray powder, the more recent ProRoot white powder (both Dentsply UK), and the white MTA Angelus (QED, Peterborough).

there is widely reported anecdotal evidence that the most profound anesthesia with rapid onset is achieved when using a local infiltration of articaine with 1:100 000 adrenaline (epinephrine). However, it has been suggested that this solution may not be suitable for an inferior dental nerve block due to the potential increased risk of paresthesia and nerve damage. It is recommended that for lower teeth an inferior dental nerve block is administered using lidocaine or other proprietary agent, with an additional buccal local infiltration of articaine. Hemostasis is greatly facilitated with an additional infiltration of lidocaine containing 1:50 000 adrenaline.

Postoperative pain control may be enhanced by the administration of 0.5% bupivacaine immediately following the surgical procedure. Although not as affective as other agents at achieving surgical anesthesia, this long-acting agent acts by reducing central sensitization following PRS. Clinical trials suggest that bupivacaine may reduce postoperative pain for up to 3 days. Non-steroidal anti-inflammatory drugs (NSAIDs) are also recommended postoperatively for pain control unless there is a medical contraindication to their use. There is no indication for the use of prophylactic antibiotics when undertaking PRS procedures other than for treating patients with a specific systemic medical condition.⁵⁹

Surgical procedures

Flap design and soft tissue management – introduction

Before a decision is made on the design of the surgical flap in any patient, careful assessment of the periodontal tissues and restoration margins is essential. Inflamed, swollen gingivae with associated bleeding on probing indicate the presence of plaque-related microbial disease. This should be addressed before treatment or postoperative outcomes may be compromised. Cause-related periodontal therapy may be supplemented with a 0.2% chlorhexidine gluconate mouthrinse twice daily (after brushing) for 1 week before and 1 week following the surgical procedure. This will significantly reduce the accumulation of plaque and enhance tissue healing.

The natural retraction of the gingival tissues following surgery with a full-thickness sulcular flap may expose previously placed subgingival restoration margins.⁶⁰ The patient should therefore be informed of this possibility in advance of the surgical procedure. If this is an unacceptable esthetic risk then an alternative flap design will be required and may involve papillae preservation. Traditionally, three mucosal flap designs have been described: semilunar, rectangular, and submarginal. Only the latter two will be considered within this chapter. The semilunar flap, where a curved incision is made over the root apices in the alveolar tissues, can no longer be advocated in endodontic surgery for a number of reasons. The semilunar incision frequently lies over the bony defect following the surgical procedure; the incision severs an excessively large number of blood vessels which run vertically through the tissues and the natural elastic and muscle fibers tend to stretch the wound margins making approximation difficult, with delayed healing and impaired esthetics.

The rectangular flap

The rectangular flap (Fig. 18.13) comprises two vertical relieving incisions with a horizontal marginal incision. Conversely, a triangular flap has only one relieving incision. However, this creates difficulty in accessing the apical tissues without applying excessive pressure to the flap which may result in tearing of the tissues. Therefore the additional relieving incision may be favored to create a rectangular flap. Although easily repositioned, the disadvantage of this flap design is the potential for gingival recession and exposure of restoration margins. It is important that the relieving incisions are placed on to sound bone.

The submarginal flap

Also referred to as the Ochsenbein-Luebke flap, the vertical relieving incisions of the rectangular flap are commenced approximately 2 mm from the gingival sulcus and the horizontal incision is made in the attached gingivae, in a scalloped pattern to follow the natural tissue contours (Fig. 18.14). This can only be

Fig. 18.13 Outline of rectangular flap.

Fig. 18.14 Outline of submarginal flap.

used where there is a good width of attached gingiva to preserve the blood supply and integrity of the remaining tissue. Any failure here and resultant necrosis of the residual attached gingiva will have catastrophic esthetic outcomes.

Microsurgical approaches

The SOM has facilitated the use of microsurgical scalpel blades and other microsurgical techniques. The potential for micro-suturing has permitted procedures designed to preserve the integrity of the interdental papilla with resultant improved postsurgical esthetics.⁶⁰ This procedure of papilla preservation is difficult and requires a good level of understanding and surgical skill (Fig. 18.11). An initial shallow incision is made at right angles at the base of the papilla through the epithelium only. The line is then retraced with the blade at an angle vertically towards the bone, leaving the papilla intact with a split-thickness incision at its base. Normal full-thickness vertical relieving incisions are then made. Micro-surgical sutures will result in an excellent esthetic result if the procedures are followed precisely and the tissues kept moist during the surgery, especially if hemostatic agents are used. However, if the incisions are made at an incorrect angle or the significance of the procedure is not fully understood, loss of the papilla may result in a worse appearance than with a conventional approach. There is early clinical evidence⁶⁰ that such papilla-based flaps achieve the best postoperative esthetic result.

Fig. 18.15 Very fine surgical elevators designed for delicately raising mucosal flaps without causing any damage to the soft tissues (left). Microsurgical instruments for curetting the underlying pathological defect (right).

Flap reflection

Whichever flap design is selected, care should be taken to retract the entire mucoperiosteal tissue without damage. Very fine surgical elevators designed for delicately raising mucosal flaps without causing any damage to the soft tissues are shown in Fig. 18.15. Starting at a vertical relieving incision, the periosteum and mucosal tissue should be elevated as one piece, bearing in mind that the surface of the underlying cortical plate may be uneven. The flap should be elevated towards the attached gingivae, with microsurgical instruments being used for gentle elevation of the gingival and papillary tissues. The flap should extend well above the anticipated position of the root apex to facilitate unhindered access to the surgical site without stretching or traumatizing the retracted tissues. Tissue retraction should follow normal surgical principles with no undue pressure, tearing or other damage to the tissues. To avoid impeding direct vision with the SOM, the vertical relieving incision(s) are made longer than in conventional apical surgery. Hard and soft tissues should be kept moist by regular irrigation with sterile normal saline throughout the operation.

Hard tissue management

Access to the root apex is frequently facilitated through a perforation of the cortical plate created by a sinus draining from the periradicular lesion. Once the flap has been raised sufficiently, the defect is identified and used as a landmark for bone removal. In those cases where such a perforation has not occurred, location can be more difficult. Clues may be found in that root tissue is harder than bone, cannot be marked with a probe, is more yellow and does not bleed. Occasionally, a methylene blue dye may be used to outline the root surface as it will stain the periodontal ligament. Careful assessment of the root length from preoperative radiographs prior to bone removal will help in locating the root apex.

Extreme care must be taken when removing bone to identify the root apex, and when extending an exposed crypt so as not to generate heat which may rapidly cause irreversible damage to the bone. Firstly, adequate and efficient coolant with sterile normal saline must be applied throughout the cutting proce-

ture. Secondly, a round bur is preferred. A fissure bur may penetrate bone which will isolate the tip from the coolant. The resultant rapid heat generation will cause, at the very least, inflammation and delayed healing. A similar adverse incident may occur if a diamond bur is used, as the grit will trap bone particles and increase frictional heat generation. Furthermore, a blunt bur will generate more heat as greater pressure is applied to cut through bone. A new surgical bur is therefore recommended for each procedure. With the improved vision afforded by the SOM, the use of micromirrors and fine ultrasonic tips, bone removal can be kept to a minimum.

A thorough and detailed knowledge of the local anatomy is essential. PRS on maxillary anterior teeth may be relatively straightforward but on mandibular anterior teeth may be far more difficult due to the shallow labial sulcus and lingual inclination of the roots. Maxillary posterior teeth present additional problems in their proximity to the floor of the sinus, although the buccal roots usually lie very close to the cortical plate and frequently perforate this. Access to palatal roots will necessitate a significantly larger osteotomy. In addition, the mandibular posterior teeth are generally covered with a thick cortical plate making access very difficult. Reports are published of failure following PRS within these anatomic regions due to necrosis of the bone. This may be attributed to the increased heat generated during the removal of significant quantities of bone.

Periradicular curettage

Periapical periodontitis is the body's natural immune response to the inflammatory mediators and infective agents within and around the root apex. Thus, no matter how thoroughly the granulation tissue that forms the PRD lesion is removed from the surgical site, unless the actual source of infection within the root canal is addressed by root resection and retrograde restoration, the surgery will likely fail. The presence of many different foreign body materials within PRD lesions has been reported by Nair.⁶² These include, of particular interest, remnants of

paper points caused by inadequate measurement during canal preparation procedures, and vegetable material entering the exposed root canal when a tooth is "left open for drainage". This procedure of "open drainage" is no longer recommended.

Every effort should be made to dissect out the granulation tissue cleanly and without damage so that it may be placed immediately in a container of formalin and sent for a pathological report. This may be accomplished using two separate instruments. A sharp curette or spoon-shaped excavator is used to carefully dissect the PRD lesion from the bony wall of the crypt (Fig. 18.15). However, this instrument is not as effective on the root surface where a sharp periodontal scaling instrument is preferred. The surgical micromirror and SOM will greatly assist when working behind the root to ensure that all remnants are released before attempting to transfer the lesion to the histological receptacle. A microscopic examination should be made to identify any remaining granulation tags. However, caution should be taken when these are attached to anatomic features such as neurovascular bundles or sinus linings.

Occasionally, the patient may complain of pain during this procedure and supplementary anesthesia may be required. Should hemostasis be inadequate, the crypt may be packed with cotton pellets impregnated with epinephrine or ferric sulfate and pressure applied for a few minutes. Both these agents provide satisfactory surgical hemostasis without any adverse effects (Fig. 18.16).⁶² Careful examination with the SOM is essential to ensure that all traces of these materials, in particular fibers from cotton pellets, have been removed before the wound is closed.

Root-end resection

The main reason for a surgical approach to an endodontic problem is to remove extraradicular bacteria and other contaminants causing clinical symptoms. However, the anatomy of the root apex is complicated, with multiple portals of exit and accessory canals. Indeed, the presence of apical ramifications may be a major contributing factor towards the occurrence of

Fig. 18.16 Hemostasis may be aided with the placement of hemostatic agents within the surgical area, for example Surgicel.

refractory PRD.⁶³ Microbial biofilms form on the root apex and these penetrate the dentinal tubules. Thus, however effective the apical curettage has been, there is a potential for recontamination, maintained inflammation, and ultimately surgical failure unless the root apex is removed.

It is generally accepted that an apical resection of 3mm will remove the majority, if not all, of these potential problem areas. This resection will additionally permit thorough inspection of the root canal, preparation of a cavity to encompass the canal shape and placement of a retrograde seal. As illustrated in Figs 18.6 and 18.17, the angle of resection should be as close to horizontal as possible (i.e. at right angles to the long axis of the tooth). This exposes a minimal number of dentine tubules, thereby reducing apical leakage and providing the best potential for healing.⁶⁴

Fig. 18.17 Large apical lesion with root apices resected at 90°. Preparation of root canal with ultrasonic tips and use of micro-mirror prior to placement of retrograde root canal filling.

The smoothest possible cut should be made, ideally using a straight fissure bur in a slow-speed handpiece. Cross-cut fissure and diamond burs tend to create a rough surface that may harbor debris, particularly remnants of the root filling material, thereby impairing healing. Ideally, the cut surface should be smoothed with a tungsten carbide or micro-fine diamond, keeping the bur moving across the root surface and not cutting backwards against the rotation of the bur. Of course, if a high-speed motor is used it must be of a surgical design with appropriate air venting. Conventional air rotor drills must be avoided in periradicular surgical procedures so as to reduce the possibility of producing pyemia or emphysema.

Root-end preparation

The preparation of the retrograde cavity has two primary objectives. Firstly, it must thoroughly remove all traces of the previous failed and contaminated root canal filling material. Secondly, it must shape the apical aspect of the root canal system in order to permit placement of a hermetic seal. This will help to prevent the exit of further microbial contaminants. Once again, good visual inspection of the root apex using the SOM, good illumination, and the use of surgical micromirrors is essential. Traditionally a micro-handpiece with a round bur was used to undertake root-end preparation. However, everyone who has performed this procedure will testify to the difficulty of preparing a cavity of at least 3mm depth that encompasses the whole of the root canal including any isthmuses. The currently preferred method involves the use of specially designed ultrasonic tips in a piezoelectric ultrasonic handpiece (Figs 18.18 and 18.19).

Ultrasonic preparation of the root end produces cleaner, well centered, and more conservative root-end cavities than conventional rotary instrumenta-

Fig. 18.18 Ultrasonic unit and close-up of ultrasonic tip used for root-end preparation.

Fig. 18.19 Ultrasonic cavity preparation of 3–5 mm of the root canal for placement of the retrograde root canal filling.

tion.⁶⁵ Various inclinations may be used to access the root apex and explore the root canal. Diamond coated tips appear to be the most effective and are more efficient in the removal of old gutta-percha. However, stainless steel tips may leave a cleaner surface with less smear layer. In the hands of an inexperienced operator, diamond tips may be more aggressive and remove excessive material. Therefore, a very gentle touch is essential using light brush strokes to plane and shape the canal. Sufficient coolant spray must be used to remove debris and prevent overheating without obscuring vision. Overheating has been a cause of concern in contributing towards micro-cracks at the root apex. Careful technique will prevent this, particularly in avoiding excessively high power settings.^{66,67} Nevertheless, even at lower power settings cracks and chipping may occur.⁶⁸

The instruments are used slowly until the desired cavity has been created, at least 3 mm deep, with clean walls uncontaminated by the old root filling material. The remaining gutta-percha at the base of the preparation should be carefully packed with a microsurgical plugger. Where two canals are present in one root it is advisable to create an isthmus between them which is filled to prevent any potential leakage. The apical preparation can then be carefully inspected with the SOM and micromirrors. The use of ultrasonics for root-end preparation has been demonstrated to improve surgical outcomes in comparison to traditional techniques.⁶⁹

Restoration of the retrograde cavity

Before restoring the root-end preparation, there must be adequate hemostasis within the surgical site. This can be achieved by placing dry impregnated cotton wool balls into the bony crypt or a hemostatic material, for example Surgicel (Johnson & Johnson, UK, Fig. 18.16). These agents also help to act as a barrier to prevent the accumulation of excess retrograde filling material around the root apex tissues. The root-end preparation can then be dried with either paper points or the use of a micro-irrigating syringe.

Fig. 18.20 Instrument for placement of MTA.

The restorative material selected for the root-end filling must be radiopaque, easy to manipulate, and exhibit two principal characteristics. Firstly, it must provide an effective permanent seal to prevent leakage from the root canal system of any microorganisms or their by-products. As such, it must be stable and insoluble. Secondly, the material should be biocompatible, ideally promoting regeneration of the surrounding cementum and bone directly on to its surface. Although many materials have been advocated for this purpose in the past, only two are now recommended as retrograde filling materials. These are MTA or reinforced zinc oxide–eugenol cements.

Mineral trioxide aggregate

As indicated earlier, MTA is now widely accepted as the preferred restorative material for retrograde root canal fillings. MTA was derived from Portland cement from which various oxides were removed to improve its biocompatibility and handling characteristics. The first MTA product introduced to the clinics was a gray material that was mixed to a gritty or sandy consistency that was rather difficult to manipulate. The latest version, white MTA (ProRoot MTA, Dentsply, UK), can be mixed to a smooth, creamy paste that is easier to place. It can be carried to the cavity in a specially designed carrier gun (Fig. 18.20a); it can be rolled into a stiff cylinder using the Lee Block (Fig. 18.20a); or carefully manipulated on a flat plastic type dental instrument directly into the cavity. Once in place, it is gently condensed. The MTA retrograde filling is subsequently finished by gentle wiping of the apical preparation with a moistened cotton wool pellet.

MTA is hydrophilic and requires moisture to set. When used within the root canal via an orthograde approach the dry conditions require a moist cotton pledget to be placed for up to 4 hours' setting time. This cotton pledget is removed at a subsequent appointment. In a retrograde cavity, absolute dryness is neither possible nor desirable, although care must be taken not to wash the material from the cavity during closure of the surgical site. It is preferable to place 3–4 mm of MTA at the root-end to provide a satisfactory seal.^{70,71} An alternative presentation, MTA Angelus, has a much faster setting time. MTA has been widely studied and is reported to be more biocompatible than any other retrograde restorative

material, inducing cementogenesis and bone deposition with little if any resultant inflammation.^{72,73}

Reinforced zinc oxide–eugenol cement

There are primarily two reinforced zinc oxide–eugenol cement materials routinely used for root-end filling (Fig. 18.21). Intermediate Restorative Material (IRM[®], Dentsply, UK) is a zinc oxide–eugenol cement with approximately 20% polymethacrylate in the powder. The second material, SuperEBA[™] (HJ Bosworth, Illinois, USA), is an alumina-fortified material in which the liquid comprises 32% eugenol and 68% ethoxy benzoic acid (EBA). Both materials are mixed to a stiff paste and packed firmly into the prepared cavity. The operating field should be dry and clean. Some clinicians have recommended cleaning the root-end cavity with citric acid or EDTA prior to restoration but as yet there is little published evidence in favor or against this procedure.

These reinforced cements have superior properties in comparison to conventional zinc oxide–eugenol cements or amalgam. They exhibit lower solubility, less leakage, and greater biocompatibility.⁷⁴ The eugenol in these materials has a localized effect upon the surrounding tissues that may cause inflammation and slightly delayed healing. However, clinical studies have produced very satisfactory results that are comparable with outcomes when MTA is used as the root-end filling material.⁷⁵ Although reinforced zinc oxide–eugenol materials appear to offer satisfactory clinical success, unlike MTA they do not stimulate any dental hard tissue or cementum regeneration.^{76,77}

Other materials

There have been several publications investigating the potential for dental adhesives such as glass ionomer cements, compomers, and composite resins, to seal resected root apices. Although there are reports that they can be effectively used in periradicular surgery,⁷⁸ there remain continuing concerns over moisture contamination preventing an adequate seal.⁷⁹ Trope *et al.*,⁸⁰ reporting research using a range of

restorative materials for retrograde obturation, expressed deep concern that even when a dry operating field was possible some moisture contamination was inevitable, compromising the seal and the outcome of the procedure. A comprehensive review of the subject⁸¹ of retrograde filling materials concludes, “The material to choose will depend on prevailing clinical conditions. For example, if there are difficulties in maintaining a dry surgical field, even if a material has excellent biological characteristics, it is unsuitable if it is sensitive to moisture.” Amalgam is no longer recommended as a material for root-end filling.

Guided tissue regeneration

There is ongoing debate as to the requirement or usefulness of guided tissue regeneration (GTR) in improving outcomes of PRS involving apicectomy procedures. From recent evidence, it would appear that the use of a GTR membrane with or without bone graft material has no additional advantage on the surgical outcome in the treatment of patients exhibiting large PRD lesions.^{82,83} Furthermore, the experimental use of bone-inducing substances, such as bone morphogenic proteins,⁸⁴ or clinical use of calcium sulfate,⁸⁵ has not displayed any enhanced benefits over natural healing. The one exception for this is in the case of a through-and-through lesion where a bone substitute and GTR may help to avoid healing of the defect site with granulation tissue (Fig. 18.22).

Wound closure

If MTA has been used as the root-end filling material, it must be carefully protected during the normal surgical practice of thorough irrigation, cleaning, and inspection of the surgical site before closure. Once the site has been inspected and any remaining foreign bodies removed, gentle bleeding may be encouraged by simple curettage to ensure a blood clot is present in the wound. The flap should be repositioned and compressed with a damp, sterile gauze swab. Once suturing is complete, similar firm compression should be applied for at least 5 minutes to ensure initial clot formation is undisturbed. To avoid wicking of bacteria into the operation site, silk sutures are not recommended for periradicular surgery. Synthetic or coated materials are preferred. Resorbable suture materials are not preferred unless the patient is unable to return for suture removal, as the rate of resorption is too variable. Interrupted or continuous sutures may be placed according to the operator’s preference. The disadvantage of the latter is that should one suture pull free from the tissue the entire flap may be loosened. Ideally the corners of the flap are initially sutured before the central part is correctly positioned and sutured. Following compression and confirmation of hemostasis, bupivacaine local anesthetic may be administered, taking great care to ensure that the flap is not disturbed in the process.

Fig. 18.21 Example of root-end filling material (IRM, Dentsply, UK).

Fig. 18.22 Extensive periradicular through-and-through defect associated with tooth 22. The soft tissue of the palate can be seen through the defect (left). Placement of a barrier membrane and bone substitute to prevent scar formation and permit guided bone regeneration at the site following surgical root resection and soft tissue curettage (right).

Postsurgical management

An example of a postoperative instruction leaflet is given in Fig. 18.23. A cold compress may be used by the patient to help reduce postoperative swelling.⁸⁶ The patient should be advised of the possible development of a limited area of ecchymosis and instructed to continue regular use of chlorhexidine gluconate mouthwashes until suture removal. Sutures should be removed after 3 or 4 days by which time periodontal fibres at the gingival margin will have reattached.⁸⁷ A postoperative radiograph should be exposed at the suture removal appointment. Good clinical governance would involve exposing a further radiograph after 1 year to confirm healing and facilitate audit of clinical outcomes. The tooth should be monitored radiographically for up to 4 years.

Following PRS procedures, the majority of patients will experience moderate pain. However, this is of a relatively short duration and occurs within the ensuing 48 hours. Postoperative pain is more likely to occur when preoperatively there is pain, poor oral hygiene, and a smoking habit.^{88,89} For pain control, non-prescription NSAIDs such as ibuprofen, unless medically contraindicated, may be taken before or immediately following surgery and continued at regular intervals for 3 days.⁹⁰ The use of such drugs on an *ad hoc* basis renders them far less effective. Severe postoperative pain is unusual, especially if long-acting bupivacaine local anesthetic has been administered. However, some patients may require codeine or similar medicament. The prophylactic administration of antibiotics is contraindicated unless the patient has a specific underlying medical condition indicating their use.

Periradicular surgery outcomes

The success of PRS has been reported to vary between 25% and 99%.⁸⁶ A recent systematic review of PRS outcomes determined that the weighted average of success was 64%, whilst the outcome from 25.7% of

Endodontic surgery

Postoperative advice sheet

1. To reduce postoperative swelling an ice-pack should be applied to your face adjacent to the site of surgery for 15 minutes in each half hour for the 6 hours after the operation.
2. Minor bleeding may occur from the site of the operation which will color your saliva. Should bleeding appear to be excessive apply pressure to the area with a moist clean cotton cloth or gauze.
3. Anti-inflammatory painkillers, such as ibuprofen, should be taken regularly for the next 2–3 days. If you are unable to take these for medical reasons an alternative medication will be prescribed.
4. Continue using the chlorhexidine mouthwash twice daily until the sutures have been removed. However, only rinse gently for the first day after surgery.
5. Follow your usual oral hygiene habits with brushes, floss, and other aids, but avoid cleaning the surgical site and only brush the adjacent teeth gently. Do not lift your lip to inspect the wound or this may delay healing.
6. Try to eat only soft food for a few days and avoid chewing anything hard with the teeth involved in the surgery.
7. Do not smoke until the sutures have been removed.
8. Please telephone the surgery if you have any concerns, in particular if bleeding persists; you suffer pain that is not controlled by the analgesics; you develop signs of infection such as a raised temperature or swollen glands.

Fig. 18.23 An example of a postoperative instruction leaflet to be given to the patient.

cases remained uncertain and 15.7% of surgical cases were unsuccessful.⁹¹ Periradicular resurgery has been demonstrated to have a significantly greater failure rate than a first surgical procedure.⁹² Repeat surgery is reported to be associated with a weighted average healing rate of only 35.7% and a failure of 38%. Furthermore, the success rate of NSRCT retreatment of failed periradicular resurgery cases is lower than NSRCT retreatment of failed endodontically managed cases.⁹³ Nevertheless, periradicular resurgery remains a valid alternative to dental extraction.⁹²

Clinical success or failure appears to be associated with the operator and the types of materials used within the surgical procedure.^{91,94} As with successful outcome following NSRCT, surgical success is directly related to the size of the periradicular lesion.^{94,95} Lower success rates are also associated with inadequate root filling length⁹⁴ and pain at initial examination.⁹⁶ Maddalone and Gagliani⁹⁷ have demonstrated that periradicular microsurgical techniques can achieve success rates of 92.5% over a 3-year observation period. It is also established that the use of modern materials, magnification, improved surgical techniques, and better postgraduate training results in improved surgical success rates over traditional PRS techniques.^{37,98} Furthermore, modern surgical techniques result in less postoperative pain compared with conventional surgical techniques but this may be counteracted with more difficulties immediately postoperatively in mouth opening, the ability to speak, and mastication.⁹⁹

Fig. 18.24 A radiograph showing a persistent lesion on the distal root of a lower molar that has not responded to orthograde retreatment. This case may be suitable for hemisection.

(a)

Other surgical endodontic procedures

Hemisection or root resection

Occasionally, root canal treatment in a multirooted tooth may be successful in one root only. This scenario is observed in Fig. 18.24. If retreatment of the affected root is not possible it may be surgically removed. However, even following careful examination of the preoperative radiograph, the root morphology may be unclear. Unless the roots are adequately separated and not fused or joined together, removal of an individual root may prove impossible. If a suture needle is threaded through the furcation and the suture tied around the crown, the separation of the roots is confirmed and the path of resection clearly marked. Once the tooth has been sectioned with a high-speed bur the diseased root may be elevated. The remaining crown may be restored as it stands or, if sufficient periodontal bone support remains, the root may occasionally be used as a bridge abutment.

Perforation repair

Perforation of the root surface may occur as a result of internal root canal resorption, by iatrogenic damage during root canal instrumentation or during post-space preparation (Fig. 18.25). The prognosis for the repair of a perforation will depend upon its position on the root, evidence of chronic infection, and presence of any periodontal breakdown and epithelial downgrowth. In endodontic retreatment cases, two factors appear to significantly impact upon successful treatment outcomes: (1) the presence of a PRD lesion; (2) the presence of a preoperative perforation.¹⁰⁰

In the first instance, repair of root perforations should normally be attempted by an orthograde approach through a conventional access cavity and

(b)

Fig. 18.25 Perforations of the root surface due to (a) internal resorption and (b) iatrogenic damage during post space preparation.

the root canal. Once again, use of the SOM facilitates detailed examination and placement of MTA. If internal examination reveals that repair is not feasible via this approach then careful note should be made of the position of the perforation. Root perforations that are labial to a line drawn mesio-distally through the tooth may be amenable to a surgical procedure. Those that lie palatal to this line will require elevation of a palatal flap and access may be severely compromised. If an orthograde approach is not considered practical, careful use of parallax radiographs, or preferably 3D CBCT, will be necessary to accurately determine the position of the perforation.

A mucoperiosteal flap should be raised as previously described. Once identified, the defect is prepared and obturated as for root-end surgery. MTA is again the material of choice for restoration of the defect. However, if a coronal lesion communicates with the oral cavity and there is the possibility of the MTA filling washing out before it has set, glass ionomer cement may be the material of choice, providing that effective isolation and moisture control are achievable. Clinical results of compromised teeth exhibiting root perforations repaired with MTA have demonstrated good outcomes in enhancing the prognosis of perforated teeth that may otherwise have been extracted (Fig. 18.26).¹⁰¹

Intentional replantation

It is sometimes possible for a tooth with a persistent PRD lesion that is not amenable to surgical repair to be extracted and intentionally replanted.^{102,103} Careful assessment of the root pattern is necessary to ensure

atraumatic removal without causing significant damage to the periodontal ligament and root surface. Prior to tooth removal, all instruments and materials required for root-end resection and restoration should be laid out to facilitate rapid treatment. The root should be carefully held with gauze moistened with sterile saline and not allowed to become dry.

As soon as the apical procedure is complete (as described for apicectomy) the tooth is replanted, the bone gently digitally compressed and the patient instructed to occlude on gauze to maintain the tooth in position as hemostasis occurs. It may be necessary to adjust the occlusion for comfort and to avoid occlusal trauma. The patient should be advised to take a soft diet, in particular avoiding sticky foods, for at least 1 week. Intentional replantation may be considered a predictable treatment when performed with care in cases where conventional periradicular surgery is not feasible.¹⁰⁴ The prognosis appears to be most related to an atraumatic extraction and protection of the periodontal ligament with a minimum treatment time.

Informed consent

Informed consent must be obtained by the clinician responsible for the provision and arrangement of treatment from all patients for all clinical procedures. She or he should have undertaken detailed audit of their treatment outcomes in order to provide a confident prognosis of the outcome for each surgical procedure. Naturally, this may include reference to general studies reported in this chapter. However,

Fig. 18.26 Repair of a root perforation using MTA. (i) Preoperative radiograph with a gutta-percha point placed in the buccal draining sinus. (ii) A large defect is evident upon raising a flap. (iii) One-year follow-up radiograph of the healed site with MTA placed at the perforation.

the patient will understandably be most concerned with outcomes related to their own clinician's procedures and results.

A detailed knowledge and understanding of endodontic principles is therefore essential when advising the patient on the choice between orthograde retreatment or a surgical approach when a root filling has failed. Should the clinician fail to obtain informed consent and treatment not be successful, the patient may seek expert endodontic opinion as to the alternative treatments available, their indications, and their respective prognoses. Familiarity with current expert opinion and practice, particularly as taught in clinical centers of excellence, is essential for all seeking to practice safely within this field.

Endodontic surgery vs endosseous implants

The dental literature has recently seen an increase in the number of published papers on this subject. In particular, some clinicians appear to consign the entire concept of periradicular surgery to history, claiming that extraction of the diseased tooth and placement of a dental implant has a better prognosis and should be the treatment of choice. Amongst these reports are two quite conflicting papers in the same issue of the *Journal of Oral and Maxillofacial Surgery*. In the first, Ruskin *et al.*¹⁰⁵ concluded that, "It is thus possible to consider early removal of teeth and placement of implants and implant based restorations as a favourable treatment option compared with the majority of endodontically treated teeth." Conversely, the authors of this chapter consider that every reasonable effort should be made to retain the natural tooth with its periodontal support, function, and proprioception, and that an implant-retained restoration should be seen as the last possible treatment option. A similar opinion is held by Thomas von Arx,¹⁰⁶ the author of the second article in the *Journal of Oral and Maxillofacial Surgery*. He discusses how microsurgical techniques, as described in this text, have contributed to higher success rates, and states that "whenever possible, teeth should be salvaged". The controversy between endodontic treatment or implant placement will no doubt continue until high-quality research evidence, which is sadly lacking at present, is published. Those interested in taking this debate further should refer to two excellent review papers.^{107,108} Both papers have similar conclusions, that the outdated concept that periradicular surgery is the "junior partner" in revision of negative endodontic treatment outcomes needs to be reconsidered.

Chapter 19

Preprosthetic and Oral Soft Tissue Surgery

Selçuk Basa, Sina Uçkan, and Reha Kışınışı

This chapter provides a comprehensive overview of various surgical procedures to improve soft tissue architecture and anatomy to improve oral function and optimize prosthetic rehabilitation in various ways, e.g. preparing a denture-bearing area and improving soft tissue conditions prior to dental implant treatment. Basic principles and recent techniques are presented.

Overview

Background

Optimal oral rehabilitation of patients presenting with functional and esthetic problems is attainable by appropriate preprosthetic soft tissue surgical procedures. A variety of surgical procedures can be planned to correct or to improve soft tissue architecture and anatomy as well as to gain desirable soft tissue features either as a denture-bearing area over alveolar bone or around dental fixtures.

Irregular and frail soft tissues, both in fully dentate and edentulous patients, need to be diagnosed in advance to avoid undesirable changes, particularly in patients who are planned to receive dental implants. Surgical management of oral soft tissues is generally carried out for esthetic, functional or curative reasons. Oral soft tissue abnormalities may be due to acquired, pathological, traumatic, congenital or developmental factors.

Progressive alveolar bone loss following tooth extraction also has effects on the covering and surrounding oral soft tissues which undergo clinical changes. The changes may necessitate modification, alteration or replacement of oral soft tissues either to host or to facilitate optimal prosthetic rehabilitation.¹

Successful surgical management of soft tissue abnormalities requires thorough anatomic and functional assessment of the overall region in order to achieve appropriate outcome and fewer denture or implant-related complaints.² The appearance, texture, histological characteristics, and quantity of oral soft tissues should be carefully assessed. Deficient attached epithelium needs to be carefully evaluated to enhance the success of restoration, which may be a removable denture or an implant-supported prosthesis.

Keratinized epithelium may need to be broadened and improved through various procedures or sometimes may be surgically modified for enhanced structural benefit.³ The anatomic zones, transitions, and features of oral soft tissues have major roles in oral

rehabilitation by all means. Current trends and oral rehabilitation philosophies have changed immensely over recent years but mucosa-supported removable dentures in edentulous cases may still be the treatment of choice for several reasons.

Among these factors, individual financial status or health system regulations are the most notable ones. The quality and quantity of the denture-bearing mucosa is a major factor for favorable retention and stabilization characteristics. Mucosa-supported rehabilitation planning relies on stable and sound soft tissues covering alveolar bone for maximal retention and stabilization for improved prognosis. Neighboring soft tissues buccally, labially or lingually also have considerable influence on the success of prosthetic construction. Non-resilient, stiff soft tissues, and functional sulcus loss, may have consequential effects on prosthetic replacements.

The surface epithelium characteristics, in terms of both quantity and quality, dictate acceptable esthetics, function, and hygiene maintenance, and successful oral rehabilitation. Deviation from normal may result from either primary or secondary causes. Primarily the surface properties, topography, texture, and structural features of oral mucosa may complicate a desirable functional result or even inhibit prosthetic rehabilitation. In these cases a surgical plan may be needed, ranging from simple revision of a localized area to an extensive reconstruction of soft tissues on and around alveolar bone.

It is mandatory to be aware of the importance of the presenting clinical features of soft tissues so as to plan and/or to predict the rehabilitation outcome. The soft tissues should be as high quality as possible to improve the end result of prosthetic rehabilitation. Therefore presenting clinical properties should be known right from the start in order to minimize or avoid patient dissatisfaction. Recognizing and differentiating pathological conditions is also of particular importance so that a proper treatment protocol can be established.

Soft tissues may need to be converted or reconstructed by tissue transfers, where staged interventions may sometimes be needed for additional adjustments or improvements so that a better prosthetic device can be fitted. Where tissues from distant sites are brought into the mouth, original features may still be seen. Skin appendages may continue to exist for some time, although, in the majority of patients who received free or distant tissue transfers, these became acceptable, especially for dental fixture placements.

The attachment properties of the overlying mucosa and underlying muscular elements on to the bone may directly affect the success of oral rehabilitation. In some cases the attachment zones of the soft tissues may be distributed in rather broad form or they may be a localized suspender close to or over the alveolar crest. According to the area affected, surgical reconstruction is needed to reposition attachment zones.

The attachment of the mucosa and width of keratinized epithelium can also change due to resorption, pathology, previous surgery or trauma.

The pattern of changes of the oral mucosa may not require any intervention in fully dentate patients, but surgical management will have to be incorporated in the overall oral rehabilitation plan in certain cases. These may range from minor detachment of the localized areas to replacement or reconstruction of wide zones, particularly for functional reasons. Functional sulcus is an important element of the oral cavity: it contributes to oral hygiene maintenance, unrestricted movement of cheeks, lips and tongue, and phonation. The loss of this area complicates rehabilitation in edentulous patients.

It should be kept in mind that soft tissue anatomy may reflect many conditions, which may accompany underlying and supportive bony abnormalities. In these instances the procedure should include bone architecture improvement strategies. These strategies not only enable improvement of the supportive bony element but also improvement or correction of the overlying soft tissue envelope. These procedures can be employed simultaneously or in a staged fashion which may require multiple interventions.

Soft tissue problems that require a surgical plan should be employed with care as sometimes a hidden medical condition mimics an otherwise simple, localized architectural change. In recent years considerable progress has been made in the selection and inclusion of cases requiring preprosthetic surgery, where an almost complete shift to implant-supported restorative concepts has been observed. Surgeons now have more alternative soft tissue improvement techniques in addition to the earlier fundamental techniques, particularly for achieving more functional anatomy for denture-bearing regions. There are also several other procedures available to improve or optimize oral rehabilitation.

History

The early attempts in the history of preprosthetic surgery started with restoration of intraoral defects by grafting procedures at the end of the 19th century. Reverdin published the first paper on epidermal grafting in 1869.³⁸ After the Franco-Prussian War of 1870–1871, Carl Thiersch worked on epidermal grafting and was able to show viability of thin grafts by microscopic observations. Thiersch's discovery in 1874, that skin could be grafted to cover wounds, played an important role in the development of soft tissue grafting. In 1894, Schnitzer and Ewald applied a Thiersch graft in the buccal mucosa. Later, in 1915, Moskowicz was first to create a vestibule by intraoral skin grafting.⁴

Kazanjian, among one of the best known pioneers in preprosthetic surgery, demonstrated a crestally based mucoperiosteal flap for buccal site vestibulo-

plasty.⁵ Weiser was cited as the first to perform maxillary vestibuloplasty by skin grafting in 1918. Submucous vestibuloplasty was also recommended by Kazanjian but the technique was later found to be quite unsuccessful.⁶ Obwegeser described a method working successfully for maxillary submucous vestibuloplasty in 1959.⁷ Kazanjian, Clark, Obwegeser, Edlan, Rumpel, Szaba, and Godwin developed various techniques for vestibuloplasty by secondary epithelialization; however most of them had unpredictable results.⁴

Meanwhile it was demonstrated that supraperiosteal deepening without skin or mucosal grafting resulted in significant deterioration in vestibular or lingual sites. Trauner and Obwegeser popularized buccal and lingual sulcus deepening by skin grafts adapted to flanges of a denture.⁸ Split-thickness skin grafting was the mainstream preprosthetic procedure performed in the 1950s to the 1970s. The rationale of grafting lingual and buccal sulcus with skin grafts was based on three main issues: (1) mechanical resistance to displacement forces; (2) stable denture-bearing area; and (3) skin as a load-bearing tissue.⁴

A reduction in the use of skin grafts occurred after the introduction of mucosal grafts in the mid-1970s. Intraoral mucosal grafts have found worldwide acceptance in clinical practice, because skin grafts have major disadvantages and morbidity. In the 1990s, the International Research Group on Reconstructive Preprosthetic Surgery was founded to establish and promote basic and advanced techniques in this field. The first major meeting was organized in Copenhagen (1997) and the second in San Diego (1999). After each meeting, consensus statements were published as the main guidelines of preprosthetic surgery.⁹

Oral soft tissue anatomy and histology

The oral cavity is the upper end and the beginning of the digestive system and has a connection with the respiratory system.¹⁰

Lips

The muscles of the lips are the superior and inferior labial muscles and the orbicularis oris. Lips are the junction between the skin of the face and mucosa of the oral cavity. The vermilion zone of the lip is the red–purple area between these two areas. The corners of the lips are usually located adjacent to the maxillary canine and mandibular first premolar teeth.¹¹ This is an extremely important area, known as the esthetic zone, which determines distribution of dental implants in the arches during placement.

The inner surface, the labial mucosa, is covered by a thick, non-keratinized epithelium. The lamina propria is wider at that site where papillae are shorter

and irregular. The submucosa contains many minor salivary glands. Dense connective tissue binds the mucosa to the underlying orbicularis oris muscle.¹²

Cheeks

The cheeks extend intraorally from the labial commissures anteriorly to the ridge of mucosa overlying the ascending ramus of the mandible posteriorly. The mucosa is non-keratinized and tightly adherent to the buccinator muscle. The parotid papilla is visible at the level of the first and second upper molars.^{11,13} Sensory innervation of the cheeks is by buccal branches of the mandibular nerve; the cheeks are supplied by buccal branches of the maxillary artery.^{12,14}

Gingiva

The attached gingiva is firmly fixed to the underlying periosteum of the alveolar bone and to the cervical level of teeth. The free gingiva lies unattached around the cervical region of the tooth. The gingiva of the maxillary anterior palate is innervated by branches of the nasopalatine nerves, whereas the posterior palate is innervated by the greater palatine nerves. The labial and buccal gingiva of the anterior mandible extending to the premolar area is innervated by the branches of the inferior alveolar nerve. The buccal gingiva of the mandibular posterior area is innervated by the buccal nerve. The lingual gingiva is supplied by the lingual nerve and vessels.

The mucogingival junction is a connection region of the attached gingiva and the alveolar mucosa. The difference in appearance and color between alveolar mucosa and attached gingiva is determined by level of translucency and keratinization. The epithelium of the alveolar mucosa is translucent and the blood vessels lie superficially. The attached gingiva is specially keratinized tissue which serves as a masticatory mucosa.^{11,14}

The floor of mouth

The floor of the mouth is positioned above the mylohyoid muscle and beneath the tongue. It is covered by non-keratinized mucosa. In the mid-anterior area, the lingual frenum connects the inferior surface of the tongue and mouth floor; sometimes it extends to lingual cortex of alveolar bone.^{11,15} In severely atrophic lower jaw, the lingual frenum should be resected to eliminate the pulling effect of the tongue. The level of the floor of the mouth needs repositioning when lingual flanges sit on the genial tubercles, which become very prominent after extensive resorption. Resection of genial tubercles can be performed 3 weeks prior to lingual sulcoplasty.

The palate

The soft palate is lined with a non-keratinized mucosa which covers connective tissue with short and broad

papillae. Conversely, the hard palate has a typical masticatory mucosa with keratinized epithelium. In the mid-palate, submucosa is missing, thus the dense lamina propria joins to the palatal bone. The existing submucosa at the connection of palate and alveolar ridge contains the greater palatal neurovascular bundles. Many minor salivary glands and taste buds are dispersed through the mucosa of the hard palate. The soft and the hard palate are separated by a well distinguished color change of palatal mucosa.¹⁶

Oral mucosa consists of two distinct layers. The external layer is a stratified squamous epithelium. This layer includes keratinized mucosa that is subjected to chewing forces. The connective tissue and lamina propria are located under the epithelium. The submucosa consists of a looser connective tissue containing fat deposits and glands. Larger nerves and blood vessels run in the submucosa.¹⁷

Primary indications of surgical procedures

Preprosthetic surgical procedures originally emerged from a need for successful construction of removable full and partial dentures. Patients were only satisfied if stability, retention, function, and esthetics were all achieved together.¹⁸ The selection of surgical procedures and their success essentially depends on the preoperative evaluation of the supporting hard and soft tissue structures and their proper preparation.

Currently surgical interventions of this nature need to address both function and esthetics. In order to attain reproducible and predictable favorable outcomes, a problem list defining all soft and hard tissue abnormalities should be noted and be managed by various methods. These may be isolated soft tissue procedures, bony enhancement or reconstructive modalities, including augmentation of deficient alveolar bone, orthodontic tooth eruption, socket preservation, or guided bone regeneration to improve overlying or neighboring soft tissues.^{19,20}

Sometimes correction of underlying bony structures may have the advantage of rearranging or improving the overlying soft tissue configuration. Therefore some surgical techniques directed primarily to the bone may almost obviate the need for soft tissue surgical reconstructive techniques. On the other hand, soft tissue corrections have to be preceded by supportive tissue or underlying structural surgical interventions in order to achieve purposeful and significant results.

The relationship of anterior dentition to gingiva and upper lip is deemed important for desirable dental esthetics. It is often impaired by an unharmonious contour of the gingival margin in the anterior region, and a disproportional relationship between lip and clinical crown length. These often require different plans although they may present concomitantly.

Anterior esthetics with an unfavorable clinical presentation may or may not require a surgical plan that primarily involves teeth and gingiva. All that may be needed in some selected patients is to address a skeletal problem and esthetics are then corrected secondarily. In such instances orthognathic surgery is executed to refine and correct improper arrangement of these elements. However the problem can be solely related to an unharmonious or distorted gingival margin where procedures need to be employed to reverse the situation. In such cases solely dealing with soft tissue may not be the treatment of choice, and soft tissue contour can be improved by bony procedures such as orthodontic eruption of relevant teeth prior to prosthodontic treatment.

In addition, sinus augmentation, bone grafting or enhancement modalities and orthognathic surgical techniques can be employed singly or in combination to address hard and soft tissue deficiencies. Corrective attempts by surgical means may sometimes play a significant role in determining the success of implants and implant-supported rehabilitation through soft tissue healing. Preprosthetic surgical procedures can include repositioning the altered muscle attachments and correction of functional sulcus loss or deficiencies where several grafting modalities may also be required. This is particularly desirable for creating an appropriate environment for the placement of implants and dentures. To accomplish primary soft tissue closure, undermining, free grafting, pedicle or free flaps are the techniques of choice, and several techniques have been described.

Understanding the relationship between hard tissue, soft tissue, and tooth position is critical for optimal esthetic implant restoration. General biological guidelines have to be considered, however the individual condition of each case should be evaluated. Another important issue is the assessment of implant sites prior to and after loss of tooth to help maintain the site in a state of esthetic predictability. If the site is not ideal, a variety of procedures using orthodontics, hard tissue reconstruction, or soft tissue corrections should be instituted to enable optimal placement of an implant.²¹ These procedures facilitate the placement of a restoration that harmonizes with the adjacent dentition.

Implant site reconstruction in the esthetic zone is essential to create an inconspicuous implant restoration. If teeth are congenitally missing, or have been lost at an early age, the site may be underdeveloped. In addition, tooth extraction following extensive infection or pathology as well as trauma may lead to alveolar bone deformities. In such instances the goal is to create an enhanced site for the restorative clinician.

The treatment modalities must be appropriate for each diagnosis, based on residual ridge position, resorption pattern, and lip support. Preprosthetic surgery has been used for a considerable number of edentulous patients for optimization of prosthetic

rehabilitation. It should be borne in mind that there is also an increase in demand of natural oral and facial postoperative function and appearance.

After surgical management of oral tumors, preprosthetic procedures may be required to improve the patient's mood and to improve quality of life by allowing completion of reconstruction.²²

Biotype conversion around both natural teeth and implants has been advocated, and the resulting tissues appear to be more resistant to recession.²³ Subepithelial connective tissue or free gingival grafting at implant sites is used to achieve a more stable peri-implant tissue particularly in thin biotype situations. Facial gingival recession of thin periodontal biotype seems to be more pronounced than that of thick biotype. Unavoidable facial gingival tissue recession is still common, however, particularly at 1 year of function.

Implant-related indications and soft tissue interactions

Soft tissue integration

Soft tissue integration as a term is used to describe the process of soft tissue healing (formation, maturation, and reshaping/adaptation) occurring around the transmucosal part of endosseous dental implants and surrounding oral mucosa. The success of osseointegration is basically judged by the quality and quantity of alveolar bone, but the quality and quantity of overlying soft tissues have an unquestionable role. Every oral surgeon knows the basic steps for dental implant placement in ample alveolar bone. Management of soft tissue problems or related insufficiencies is the key to long-term success. Establishment of an esthetic and healthy peri-implant soft tissue interface should be the primary goal of implant therapy. Long-term predictability and patient satisfaction could be obtained by creating a stable peri-implant environment, using basic and advanced surgical procedures such as soft tissue augmentation, flaps, and periodontal plastic procedures.

Surgical management of peri-implant soft tissue

Implant-related indications

Preservation of healthy peri-implant soft tissue is an important and challenging part of dental implant treatment. It is achieved by tight adaptation of oral mucosa to the marginal section of a dental implant, forming a natural soft tissue barrier. The existence of any periodontal pathology will result in structural breakdown of this soft tissue barrier, and this promotes the onset of a peri-implant disease.

Careful evaluation of peri-implant soft tissues includes determination of quantity and quality of attached gingiva, which can be performed with a periodontal probe during bone mapping prior to implant insertion. Implant-related indications for soft tissue surgery include lack of soft tissue volume around implants, presence of hypertrophic gingiva, esthetic reasons, inadequate vestibular depth, and inadequate depth of lingual sulcus.

Mucosal or mucoperiosteal flaps are developed according to the type of existing soft tissue problem. The incisions should be placed at the crestal level in order to leave adequate amounts of keratinized and well perfused mucosa at both buccal and lingual sites. The criteria for incision and flap development vary according to whether the marginal bone level of the implant is submerged or non-submerged. A palatal incision is preferred to hide the incision line and prevent any mucosal fenestration of submerged implants during the osseointegration period (Figs 19.1 and 19.2). In contrast, a crestal incision is widely accepted to facilitate soft tissue adaptation around necks of non-submerged implants.

Papilla regeneration

The papilla regeneration technique is a simple and innovative method to form a new papilla between implants or teeth. The vestibular flap is used as a donor site, and a small semi-lunar flap developed from the vestibular flap is rotated mesially or distally

Fig. 19.1 Flap design for edentulous maxillary arch.

Fig. 19.2 Flap design for total edentulous mandibular arch. The dotted lines indicates the vertical releasing incisions if needed.

Fig. 19.3 The papilla regeneration technique described by Pallaci.

where formation of a new papilla is desired (Fig. 19.3). A small palatal or lingual crestal incision is made to uncover the implant and, immediately after a healing cap is inserted, a semilunar incision is performed and rotated.²⁴

Oral soft tissue grafting

Success of oral soft tissue grafting mainly depends on vascularization of a graft at the host site, graft immobilization, host site hemostasis after graft fixation, and graft thickness. Vascularization of full- or split-thickness soft tissue grafts occurs in two stages: plasmic imbibition and inosculation of blood vessels. Plasmic imbibition is the first process of graft healing in which plasma-like fluid accumulates under the graft and is absorbed by thin inner endothelial cells. This absorption continues over 48 hours, while a fibrin network and blood flow are established. In the second phase, vascular buds inosculation with arteries

and veins in the graft and anastomoses develop between the host and the graft.¹⁹

The host region should provide proper vascularization properties for graft integration. Exposed implant surfaces or thick scarred mucosa are poorly vascularized areas that should be covered with flaps retaining their blood supply, such as a vascularized periosteal connective tissue flap or a lateral advancement flap. Immobilization of a transplanted graft increases the chance of graft survival. Mobility of a graft prevents establishment of microcirculation between the host site and the graft. Active hemorrhage after graft fixation prevents formation of blood clots and adaptation of the graft to the host site.

The graft should be large and thick enough to cover the denuded region. The size of the graft should compensate for postoperative contracture. The thinner the graft is, the better it is incorporated at the host site. Thicker (full-thickness) grafts are suitable for closure of abutments or healing caps.

Fig. 19.4 Schematic representation of onlay palatal mucosa grafting to form peri-implant attached mucosa at the neck level of implants.

Fig. 19.5 (a) Palatal mucosal graft adapted to the host site. (b) Free palatal graft increased the width of labial attached gingiva and gained extra support against peri-implant flora and lip stretching.

Palatal mucosa grafting

Mucosal palatal grafts were used successfully for years in periodontal practice to cover denuded roots. A similar philosophy is applied to dental implants which have loose alveolar mucosa on their labial sides. The quality and amount of attached gingiva determines the predictability of peri-implant soft tissue inflammation. Restoration and maintenance of an acceptable band of attached gingiva around dental implants is essential for satisfactory outcome from implant therapy (Fig. 19.4).

The general technique for obtaining keratinized peri-implant soft tissue is application of palatal mucosal grafts which have superior resistance to inflammation at the crestal level. Split- or full-thickness palatal grafts can be harvested (Fig. 19.5). In severely atrophied jaws, gingival grafting should be performed prior to implant placement when the height of the mandible is less than 10 mm and has less than 3 mm attached gingiva.

Subepithelial connective tissue grafting

Ridge augmentation by connective tissue grafts is used for enhancement of esthetic appearance of soft tissue surrounding abutments. Biologically, subepithelial connective tissue grafts (SCTG) exhibit superior ability to heal in grafted sites since the graft is interposed between split-thickness upper layer and the periosteum so it receives its perfusion from both sites.²⁵

For convenient grafting, the SCTG should be 1.5–2 mm thick. Multiple pieces of varying size and shape could also be used for correction of soft tissue

Fig. 19.6 The double incision technique to retrieve an SCTG from the palate. (a) Horizontal, initial incision. (b) Second, beveled incision. (c) Harvest of connective tissue with a scalpel.

Fig. 19.7 Bruno's technique for harvesting an SCTG. (a) First short incision. (b) Beveled vertical incision to remove the graft from the base.

deformities. Several techniques have been described for SCTG harvesting, of which Bruno's method (Figs 19.6 and 19.7),²⁶ open door technique with broad-band pedicle or with narrow base (Fig. 19.8), and double-scalpel technique²⁷ are mostly used. Greater palatal vessels may be endangered during harvesting of connective tissue, therefore the donor site should not be prepared too far distally.

Fig. 19.8 The open-door technique for a SCTG harvest.

Fig. 19.9 Reconstruction of a soft tissue defect on the buccal side. (a) Creation of palatal and buccal flaps. (b) A connective tissue graft is inserted under deficient mucosa.

In Bruno's method two incisions are used:

1. Initial, paramarginal horizontal incision which is made down to the palatal bone.
2. Second, beveled or vertical incision in which scalpel touches palatal bone and goes 10mm deep parallel to the tooth axis (Fig. 19.6).

The periosteal elevator dissects the connective tissue with attached periosteum and primary closure of flaps is obtained at the donor site (Fig. 19.7).²⁶

After harvest of SCTG, flaps are prepared at the host site and the graft is submerged. At least 3 weeks are required for optimal healing before any prosthetic or surgical procedure is carried out. The grafting technique is described in Figs 19.9 and 19.10. Modification of this procedure includes rolling of a pedicled SCTG graft under a buccal flap.

Vascularized periosteal connective tissue flap

The vascularized periosteal connective tissue flap offers reconstruction of large soft tissue deficiencies

Fig. 19.10 (a) Mucosal depression on the buccal gingival band. (b) Design of an incision. (c) Harvest of a connective tissue graft from the palate. (d, e) Insertion of the graft and slight roll-up of the flap over the abutment. (f, g) Postoperative view of the grafted gingiva during prosthetic treatment.

(j) Final view after soft tissue closure.

at the anterior maxillary ridge. The amount of transferred tissue is capable of reconstructing the compromised region in both the horizontal and vertical planes (Fig. 19.11). The size of pedicle is determined by the requirement of soft tissue reconstruction. The rotated flap brings its blood supply within the connective tissue envelope, thus perfusion is enhanced during the healing period (Fig. 19.12). The advantages of rotating a vascularized connective tissue flap are reconstruction of soft and hard tissue at the same time, short healing period, and treatment of scarred tissue in the esthetic zone.¹⁹

Minor preprosthetic procedures

Before fabrication of dentures, it is essential to evaluate skeletal discrepancies of alveolar or palatal processes. Any soft tissue impingement under flanges caused by irregular bony topography would create extreme difficulty for patients during oral functioning. The bony aberrances may be sharp-edged, lobulated or broad, and may disturb the health of overlying mucosa, compromising its structural integrity with progressive fibrotic transformation and irritation due to inflammation.²⁸

Tori on palatal and lingual sides may cause extra discomfort by preventing seating of dentures. Slightly larger and active frena on lingual and buccal sides may interfere with seating or dislodgement of dentures. Again, sharp-edged mylohyoid ridges or alveolar crest may be responsible for continuous irritation and pain during occlusal forces. Epulides on the maxillary vestibule are also sources for infection, irritation, and pain, and they must be removed before impressions are taken. The aforementioned situations are observed very often in clinical practice and it is imperative to resolve underlying bony or soft tissue problems before prosthetic treatment proceeds further.

Alveoloplasty along with tooth removal

Preservation of alveolar bone during extraction of a tooth is the main objective of a general practitioner. An attempt to prevent loss of marginal alveolar bone by grafting the empty tooth sockets and covering grafted sites with resorbable/non-resorbable membranes was practiced in the past, but it is not recommended due to its questionable success.

Extraction of fractured tooth apices is problematic because surgical removal will cause inevitable destruction of residual alveolar bone in the apical area. If the apex is uninfected and root is small it would be better to leave the root. Another problem mostly encountered after multiple extractions is postextraction irregularity of alveolar sockets. The irregular surface may be trimmed with a bur, a rongeur, a fine osteotome or a bone file. A horizontal

crestal incision with two releasing incisions is made to provide access. Great care is taken during flap elevation since soft tissue is tightly adapted to undercuts of irregular bone. Whenever possible, it is better to use a file or rongeur in minor discrepancies to prevent decrease of alveolar height. Excessive trimming may cause filling of sockets with mucosa which later results in decrease of bone height.

The maxillary alveolar process that is inclined buccally results in additional difficulties such as blocking the intraoral route of dentures. In severe lateral projection, mucoperiosteal flaps are developed from both buccal and palatal sites. After interdental septa are removed with a hard bur, two vertical bony cuts are made on the buccal alveolar wall and palatal sites which help to weaken the alveolar process. Unfortunately, removal of interdental septa inhibits growth of endosteal bone which is important to preserve the ridge form.

The alveolar process is squeezed with the fingers to create green-stick fractures on both sides. The flaps are sutured and the ridge is stabilized. In cases with less inclined maxillary ridges, it is logical to perform buccal wall corticotomy only on the buccal side. The edges of the mucoperiosteal flap are trimmed, reduced, and closed in primary fashion. Resorbable running or lock stitch suture could be used for closure.

Treatment of exostosis

Exostosis of alveolar bone is a benign osseous hypertrophic formation. The exostosis occurs more commonly in the maxilla. Large undercuts may also be present after extractions. Secondary alveolar recontouring is indicated in such cases. A mucoperiosteal flap is elevated after adequate infiltration of the mucosa. In large exostosis, an anesthetic block of the inferior alveolar nerve may be required. An envelope flap is developed with a vertical releasing incision not going too deep in the vestibule. The bone is resected and smoothed with an osteotome or a bur.

If implant placement is considered appropriately at crests with exostosis or undercuts, the defects under these irregularities are treated with autogenous bone grafts or guided bone regeneration.

Reduction of genial tubercles

The genioglossal muscle attaches to the genial tubercle located at the lingual aspect of mandible. As the mandible resorbs, the genial tubercle becomes prominent and the mouth floor ascends simultaneously with the resorption process. During fabrication of dentures, the activity of the genioglossal muscle and protuberance of the genial tubercle complicates wear of dentures by causing dislocation during function. Lingual flanges have to be made shorter to avoid direct pressure on the prominent genial tubercle, and short flanges result in inadequate prosthetic retention. Lowering of mouth floor procedures could also

be considered when the genial tubercle and genioglossal muscle interfere with retention and stability of a prosthesis, but this technique is no longer recommended.²⁹

A crestal incision is performed with a #15 scalpel along the anterior ridge. Subperiosteal dissection is continued under the lingual mucoperiosteum until the genial tubercles and muscles become evident. Sharp dissection of the genioglossal muscles is performed with monopolar cutting electrocautery in order to control any hemorrhage from the muscle. The genial tubercle is resected with a fissure or round bur. Strict hemostasis should be obtained prior to closure of the lingual flap otherwise life-threatening airway restriction may occur due to hematoma formation in the floor of the mouth.

Reduction of mylohyoid ridge

In extensive resorption of the mandible, the mylohyoid ridges become prominent and contribute significantly to denture displacement with strain of the mylohyoid muscles. Pain is felt because of mucosal impaction of dentures at the sharp mylohyoid ridges. With the introduction of dental implants, lowering of the mouth floor and reduction of the mylohyoid ridge became a historical procedure. However, in sporadic cases, indications still exist for surgical resection of sharp ridges.²⁹

After accomplishing lingual, inferior alveolar, and buccal nerve blocks, a crestal incision is made along the posterior mandibular ridge. Subperiosteal dissection is carried out to expose the mylohyoid ridge and muscle. The attachment of the mylohyoid muscle to the ridge is grasped with a curved clamp and the muscle is separated by electrocautery. The mylohyoid ridge is smoothed or resected with a bur. At this stage, if lowering of the mouth floor is going to be performed, the lingual flap is sutured percutaneous to skin of the submandibular crease with a Reverdin needle. If sulcular deepening is done on the buccal side, the lingual flap is sutured to the edge of the buccal flap. Lowering of the mouth floor is a historical procedure; it is not used routinely any more.

Removal of tori

Palatal and lingual exostoses are known as "tori". Lingual tori are generally bilateral and can be singular, lobulated or multiple. These benign osseous growths should be removed prior to dentures being contemplated. The lingual tori are accessed with horizontal crestal incision. Vertical incision must be avoided as much as possible since perfusion of thin overlying mucosa could be affected. The lingual torus can be removed with a bur or an osteotome. It would be of benefit to place gauze under the tongue to prevent hematoma formation.

Palatal tori of unknown etiology are observed mostly in the middle of the palatal vault. The inci-

dence in women is twice that in males. Palatal tori can be broad, lobulated, or nodular. Indications for removing the palatal tori are:

- large nodular and lobulated tori interfering with seating of dentures;
- torus with traumatized mucosal surface;
- torus extending beyond the palatal region;
- torus with deep undercuts and multiple nodules;
- torus that complicates speaking;
- psychological problems.

Before contemplating a torus operation on the palate, an impression is taken and a translucent surgical stent is fabricated. The patient should be informed about the possibility of formation of an oroantral fistula in the postoperative period, since the mucosa overlying the palatal torus could be very thin and susceptible to perforation.

Various incisions have been described for removal of palatal tori. A C- or U-shaped incision, open-door technique (double Y incisions over tori) or palatal flap technique could be chosen, according to the type and height of tori. After infiltration of the major palatal nerves and nasopalatine nerve, an incision is made and a subperiosteal flap is elevated. Small tori are removed with a round bur but large tori are sectioned first with a fissure bur and then removed with an osteotome or egg-shaped bur (Fig. 19.13). Extra care is taken to avoid extensive removal of palatal bone and subsequent perforation of the nasal floor. The flaps are sutured in a primary fashion after copious irrigation with saline. The surgical stent is applied with a tissue conditioner to avoid formation of a hematoma and dead space under the stent.

Recontouring of soft tissues

Maxillary tuberosity reduction

Enlargement of the maxillary tuberosity may occur due to soft tissue bulking. Increase in vertical dimension at the posterior ridge may limit the intermaxillary space required for denture construction. With enlargement of the maxillary tuberosity, pneumatization of the antrum may descend into the tuberosities. Pneumatization of sinuses must be checked with a panoramic radiograph prior to surgical reduction. Entrance to the maxillary antrum would not complicate the procedure.

A wedge-shaped resection of excessive tuberosities is performed (Fig. 19.14). Two elliptical incisions are made and a subperiosteal dissection is continued to the tuber maxilla. Excessive submucosa is undermined with sharp dissection and removed from the buccal and palatal flaps. Removing submucosal contents is important for approximation of flaps on both sides (Fig. 19.15). Antral communication during bone removal is not a problem if the antrum is free of any disease, infection, etc.²⁹ The surgical field is irrigated

Fig. 19.13 Removal of a palatal torus. (a) Design of an open-door incision. (b) Sectioning of the hard nodules with a fissure bur. (c) Smoothing the palatal bone with an egg-shaped bur. (d) Final closure.

Fig. 19.14 A wedge-shaped elliptical excision for tuber reduction.

copiously, and buccal and palatal flaps are trimmed to prevent overlapping and closed primarily.

Frenectomy

Various techniques have been described for removal of active and strong frenum attachments. These are V-Y advancement flap, Z-plasty, and diamond-shaped excision.

The diamond-shaped excision is usually used and provides optimal results. Local anesthetic with epinephrine is injected into the mucosa adjacent to the frenum. Direct injection into the frenum is avoided since anatomical borders may disappear, and result

Fig. 19.15 Reduction of an abundant maxillary tuberosity. (a) Redundant soft tissues of the maxillary tuber. (b) The wedge excision. (c) Undermining the submucous tissues. (d) Final closure.

in excessive excision of mucosa. Eversion of the upper lip also helps to identify borders of a frenum. In the diamond-shaped excision technique, two hemostatic clamps are applied to the superior and inferior section of the maxillary midline diastema. With a #15 scalpel, the clamped tissue is resected immediately from the mucosa. The upper vertical incision is closed with simple sutures and the inferior part, localized at the attached gingiva, is left to heal secondarily (Fig. 19.16).

Fig. 19.16 (a) A labial frenum. (b) The excision is performed adjacent to a clamp. (c) Residual defect after excision. (d) Suturing upper end of the wound, the lower raw surface is left for secondary epithelialization.

The Z-plasty technique may produce less scar than the diamond-shaped excision. Z-plasty is usually indicated for a frenum with a wide crestal part and shorter alveolar height because it increases alveolar height. An incision is made directly along the length of a frenum. Superior and inferior incisions are placed to form triangles. After supraperiosteal undermining, the apex of the inferior triangle is rotated upwards and conversely the apex of the superior triangle is rotated downwards (Fig. 19.17).

If the frenum is broader, localized vestibuloplasty offers better results compared to the above techniques. An incision is placed at the base of a frenum and the frenal attachment is elevated with supraperiosteal dissection. The area is left to heal by secondary epithelialization.

Lingual frenectomy (tongue tie, ankyloglossia treatment)

In edentulous older patients, the lingual frenum may attach high at the crestal level. This attachment may cause speech difficulties and denture instability. The mouth floor is infiltrated with local anesthetic. A

suture is placed in the tip of tongue for reflection and exposure of the lingual frenum. The most important anatomical structures are the orifices of Wharton's duct and the vascular network of the mouth floor. Connective tissue at the base of the tongue is released with a scalpel or electrocautery and blunt dissection is performed with dissecting scissors to enable approximation of flaps. Fibrotic tissue starting from alveolar ridge to the base of tongue is then resected while additional attention is paid to tissue between sublingual carunculi. It is preferred to close the area with resorbable sutures.

Removal of palatal papillary hyperplasia

Papillary hyperplasia of palatal mucosa is a pathologic condition of unknown etiology and mainly occurs with ill-fitting dentures. Day-long wearing of dentures may be responsible for the condition, however the disease is observed also in patients who do not wear their dentures for 24 hours a day. Papillary hyperplasia is presented with reddish small nodular inflammation and edema of palatal mucosa. Mechanical irritation seems to be an initial factor,

Fig. 19.17 The Z-plasty frenectomy technique. (a) Outlining of the Z flaps. (b) Creating the small triangular flaps. (c) Rotation of the flaps and final closure.

however isolated cultures from lesions demonstrate predominance of *Candida albicans*, a species that increases in mouths with poor levels of oral hygiene.

An initial therapy is removing ill-fitting dentures or relining dentures with tissue conditioners over a 6-month period. Anti-fungal ointments may be used to eliminate candidiasis. Nystatin or clotrimazole are drugs of choice. In advanced stages of papillary hyperplasia, surgical excision should be accomplished with the following methods: rotary instruments, debridement with scalpel, electrocautery, and laser resurfacing.

Vestibuloplasty

Preprosthetic surgery attempts to create an oral environment that can properly support a functional prosthetic appliance and should be considered as an essential component of prosthetic reconstruction. Difficulties faced in the prosthodontic rehabilitation of a patient are re-establishment of the best masticatory function combined with restoration or improvement of dental and facial esthetics.

The factors affecting bony and soft tissue changes are:

1. General factors – systemic bone disease, nutritional abnormalities.
2. Local factors – size, shape of alveolus before and after extraction, effects of ill-fitting prosthesis.

A thorough and comprehensive examination, diagnosis, and treatment plan will reveal that surgical intervention prior to commencement of prosthodontics can improve the prognosis of patients. Detailed intraoral examination and review of medical history, physical evaluation, discussion with the patient about his/her chief complaint, goals and expectations for long-term function and esthetics, psychological factors, and level of patient's surgical risk should be considered while developing a treatment plan. As a general rule the best procedure to choose is the least invasive one offering predictable clinical success.

Oral evaluation should include bony evaluation and soft tissue evaluation:

1. Bony evaluation: evaluate height, width, and general shape of alveolar ridge and underlying basal bone; locate undercuts, neurovascular bundle, and concavities.
2. Soft tissue evaluation: lesions which require biopsy, attached mucosa, flabby tissue, frenum attachments.

The main objectives, goals or premises of preprosthetic oral soft tissue surgery are preparation and enhancement of denture seating area by providing optimal soft tissue conditions and deepening of flange region that increases resistance to displacement forces. Types of preprosthetic surgery can be classified in a number of ways. One method is to categorize the

surgery as resection, recontouring or augmentation of bony or soft tissue.

Increase of the occlusal load-bearing region and reduction of vertical alveolar bone resorption should be measured as a secondary purpose in performing reconstructive surgery.

Preoperative evaluation

Psychological evaluation

Preoperative preparation plays an important role for the success of procedures. Patients who require vestibuloplasty often complain about lack of functional chewing and loss of significant retention of their dentures. Preprosthetic surgery helps when the problem with retention is confined to aberrant intraoral anatomical topography. An initial interview would be very beneficial to understand whether the surgery would meet the patient's expectations. It might be possible to determine if patients have maladaptive behavior or neurotic anxiety that could not be altered with a surgical intervention. In such cases, referral to a psychologist would be logical.

Radiographs

Panoramic and cephalometric radiographs would be beneficial to determine vertical alveolar bone height in the mandibular symphysis and corpus regions: 15mm or more of mandibular body is considered to provide the desired vestibular sulcus after vestibuloplasty.

Benign soft tissue lesions

Hypertrophic/exophytic benign soft tissue lesions should be treated prior to flange deepening. Papillary hyperplasia, epulis fissuratum or chronic traumatic ulcers are common pathoses and must be managed several weeks before the vestibuloplasty operation. Cryotherapy, excision, electrocautery, and laser ablation may be techniques of choice.

Management of sharp mylohyoid ridges and genial tubercles

A sharp mylohyoid ridge requires reduction during lowering of the lingual sulcus, however osseous resorption generally occurs simultaneously after dissection of the mylohyoid muscles. Resection of mylohyoid ridges should not be performed unless prosthodontic consultation is obtained, since the undercuts of mylohyoid ridges provide noteworthy retention for dentures. In the same way, sharp genial tubercles usually atrophy after dissection of genio-glossal muscle. These tubercles should be recontoured 2 months before a graft-combined-sulcoplasty procedure is performed.

Surgical techniques

Ridge extension can be achieved by numerous techniques as appropriate for the maxillary and the mandibular ridges. Both local and systemic factors affect choice of the right surgical technique. The condition of recipient and donor sites, height and shape of the underlying alveolar bone, and amount of surgical dissection determine the worth of mucosal or split-thickness skin grafting.

After the Consensus Conference in Berlin, in 1983, the necessity of covering the periosteum was no longer discussed.³⁰ Covering the raw vestibular periosteal surface with a skin or mucosal graft and screw fixation was considered as the main objective. Otherwise, complete relapse could occur during secondary healing with scar contraction and epithelialization of the vestibular periosteum.^{4,31} Fast growing interest in implantology has restored the importance of the pedicled flap vestibuloplasties used in combination with implants.^{32,33}

Procedures for sulcular deepening are listed as below:

- With soft tissue grafts: mucosal graft, palatal graft, split-thickness skin graft, meshed skin or mucosal grafts.
- With pedicled mucosal grafts:
 - submucous vestibuloplasty;
 - crestally or inferiorly pedicled mucosal flaps.
- Secondary epithelialization.
- Mouth floor lowering with mylohyoid and genio-glossal muscle repositioning. No longer a recommended procedure.
- Mylohyoid repositioning.
- Creation of post-tuberosity (hamular) notch.
- Any appropriate combination of aforementioned procedures for the maxilla and mandible.

Free grafting techniques

Split-thickness skin grafting

A split-thickness skin graft, which is totally excised from its underlying blood supply, is composed of dermis and epidermis. Full-thickness skin grafts are composed of dermis and all the epidermis, which contains hair follicles, adnexal structures (sweat and sebaceous glands), and skin capillaries. Split-thickness skin grafts are subdivided according to thickness of the dermis: thin, intermediate or thick grafts.⁴ The thickness of grafts is determined by settings of a dermatome at 10 to 25 thousandths of an inch, transparency of a graft, and bleeding of the donor site. The thinner a skin graft, the more rapid vascularization and the more contracture occurs.⁴

Split-thickness skin grafts are mainly used in combination with a vestibuloplasty, and were used in lowering of the floor of the mouth in the past.³⁴⁻³⁷ Skin grafting for vestibular deepening was presented first by Reverdin in 1869.³⁸ Trauner and Pichler pub-

lished a detailed article revealing many aspects of this procedure in 1930.³⁹ Schuchardt demonstrated labiobuccal skin grafting without creating a skin-lined pouch in the vestibular sulcus.⁴⁰

Full-thickness skin grafts in the oral cavity are not as ideal as split-thickness skin grafts because they frequently display hair growth and keratinization, and patients are often disturbed by their color, taste and smell.⁴¹

Surgery starts with a mucosal incision from the left to the right molar region. The muscle fibers in the subcutaneous tissues are dissected from the periosteum and the mental nerves are protected. Supraperiosteal dissection must be limited to two thirds of the mental muscles in order to avoid chin ptosis.⁴² At least 5 mm of muscular pedicle (or 10 mm of soft tissue) should be kept intact to the periosteum to prevent sagging of the chin.⁴³

The skin donor sites are the hip⁴ and the retroauricular area.⁴⁴ Larger grafts can be obtained from the hip. Fixation of the grafts is performed by surgical stents, sutures, and fibrin sealants.⁴⁵ The skin is adhered to the inner side of the sterilized stent with wet cotton applicators. Tissue conditioner, such as Visco-Gel, can be combined with the stent to achieve proper sulcular shape and faster healing. The stent was secured in the past by circumpalatal or circummandibular wire fixation; however that concept was terminated after the Consensus Conference.³⁰ The stent is generally removed after 7–10 days. During that period, antibiotic cover should be provided and intraoral saline irrigation should be continued for 2 weeks.

Palatal grafts

The most preferred intraoral soft tissue graft is the palatal mucosa which heals perfectly.^{32,46} Palatal grafts can be used as an alternative to skin grafts. The graft can be harvested with a #15 blade or a mucotome. A graft is sutured on to the periosteum with resorbable sutures. Four to six strips of palatal graft have to be removed for a total vestibuloplasty. The fixation of a splint is done in the same manner as for split-thickness skin and mucosal grafts.⁴⁷

Local anesthetic is injected supraperiosteally to the donor sites. With a #15 blade, the incision lines are outlined and cuts are performed supraperiosteally. Lamina propria and submucous fatty tissues are dissected from each other with the #15 blade or dissecting scissors. After the graft is taken out, it is thinned by removing excessive fat tissue and minor salivary glands. The graft is rolled up in a saline-soaked gauze. The donor site is irrigated and any bleeding from the major palatal vessels is investigated. If such a complication is present, hemostatic agents, “stick-tie” ligation or electrocautery is often effective and provides satisfactory hemostasis. The graft must be fenestrated at two to three sites to allow regress of seroma or hematoma which may prevent adherence of the graft to the periosteum (Fig. 19.18).²⁰

Fig. 19.18 Vestibuloplasty with palatal mucosa grafting. (a) Preoperative view of shallow vestibular sulcus. (b) Supra-periosteal dissection. (c) Suturing mucosal flap to the deepest level at the newly formed sulcus. (d) Marking the palatal mucosa prior to harvest. (e) The harvested palatal mucosa. (f) Healing after 1 week. (g) Complete healing of the palatal grafts. (h) The newly formed vestibular sulcus.

The advantages of intraoral palatal grafting are: (1) histologic similarity to adjacent intraoral soft tissues; (2) ease of harvesting; (3) lack of hair follicles or sweat glands; and (4) limited morbidity. The disadvantages of palatal mucous grafts are: (1) limited tissue; (2) bleeding from injured palatal vessels; and (3) donor side morbidity if dissection has gone too deep.⁴

Meshed skin and mucosal grafts

Meshing of split-thickness skin or mucosal grafts helps to cover large areas when donor sites are limited.⁴⁸ Meshing allows expansion of the graft up to nine times the surface area of the donor site. The slits in the meshed skin graft allow wound fluid to escape through the graft rather than accumulating beneath it and preventing adherence. Since introduction of machine-meshed skin grafts,⁴⁹ many other techniques and modifications have evolved to aid in the procedure.

After harvesting and thinning, the mucosal graft is meshed with a graft expander or manually. A common method of meshing a split-thickness skin graft is to make multiple cuts with a #15 blade to the graft laid on a hard, wooden board. The expansion slits heal by re-epithelialization and may contract significantly. When healed, the grafted site characteristically has a "crocodile skin" or "checkerboard" appearance.

Mucosal grafts

The donor site of mucosal grafts is the inside of the cheek. The submucosal fat and connective tissues are removed with scissors and tweezers. The cheek is closed primarily with a resorbable suture. The disadvantages of mucosal grafts are lack of attached mucosa that weakens resistance to infection and allows mucosal movement.⁵⁰

Pediced flaps

Kazanjian's vestibuloplasty

A transvestibular horizontal mucosal incision is made in the lower lip between the right and left premolars. The mucosa is dissected suprapariosteally to the alveolar crest, which is followed by suprapariosteal dissection of the mental muscles to the vestibular depth. The pedicled flap is sutured to the periosteum to the depth of the vestibular sulcus. The open wound in the vestibular sulcus and inner lip is left to heal by secondary epithelialization (Fig. 19.19). This method can be used with or without simultaneous insertion of dental implants.⁶ A novel modification⁵¹ was reported to eliminate formation of a V-shaped pocket in vestibular depth.

Although overcorrection has been recommended due to the relapsing tendency of Kazanjian's^{5,6} and Clark's vestibuloplasty,⁵² it is not always possible

Fig. 19.19 Kazanjian's vestibuloplasty. (a) The crestal pedicled flap is raised from the inner side of the lip. (b) The flap is sutured over the periosteum to the deepest point of dissection.

Fig. 19.20 Edlan's vestibuloplasty (lip switch technique). (a) The crestal pedicled flap is raised from the inner side of the lip. (b) The flap is sutured over the periosteum to the deepest point of dissection. (c) Final result after flap transpositioning.

to create a deep sulcus due to insufficient height of alveolar bone. Epithelial grafting of raw surfaces in the dissected vestibule decreases the secondary contracture and postoperative relapse during re-epithelialization.⁵³

Transpositional flap vestibuloplasty (lip switch or Edlan vestibuloplasty)

The lingual-based flap vestibuloplasty was first described by Kazanjian.⁵ The technique underwent a modification with covering the denuded region of lip that was left to secondary epithelization in the initial technique.⁵¹ This procedure is indicated primarily for the patients with insufficient mandibular vestibular depth and adequate lingual sulcus.⁵⁴

The standardized Edlan vestibuloplasty has an important role in preprosthetic surgery.²⁹ An incision is made through the mucosa from one premolar region to the inner lower lip and from there to the contralateral premolar region. The mucosa is prepared to the highest point of the alveolar ridge; the periosteum is incised at the alveolar ridge and prepared down to the required vestibular depth under direct vision of the mental nerve. The periosteum is sutured to the mucosal crest of the inner lip. The pedicled mucosal flap is sutured to the periosteum to the vestibular depth. This method is mainly used in combination with the insertion of implants (Fig. 19.20).

The lip switch technique could be combined with a surgical splint; however the patient's own denture could also serve as a retention splint if it is relined

with a soft tissue conditioner to obtain proper adaptation of vestibular sulcus. The disadvantages are scar contracture and unexpected relapses which occur in up to 50% of cases. Vertical resorption of the underlying alveolar bone is another complication with this procedure.^{4,31,55–57}

Submucous vestibuloplasty

Submucous vestibuloplasty was first described for the mandible; however the procedure was found to be quite unsuccessful.⁶ The submucous vestibuloplasty has been recommended for deepening the maxillary vestibule.⁸

Closed submucous vestibuloplasty technique (Obwegeser)

An incision is made at the midline of the maxillary arch and a layer above the periosteum and below the mucosa is dissected. The superficial plane is created anteroposteriorly with scissors until translucency of the buccal mucosa is observed. The length of the superficial dissection is carried out as far anteroposteriorly as the anatomy will allow. The secondary plane is formed with a periosteal elevator. The intermediate soft tissue is separated and moved superiorly (Fig. 19.21). Otherwise, wedge or complete excision could be performed. The thin mucosal flap is adapted directly over the periosteum and, with the help of a surgical stent, the flap is secured for a week. The

Fig. 19.21 Dissection of the superficial and the secondary deep plane is performed through a short vertical incision at the midline of maxillary vestibule.

Fig. 19.22 A surgical stent is secured to the upper arch with two titanium screws for 7–10 days.

sharp anterior nasal spine can be also smoothed with a rongeur or a bur. A figure-of-eight suture is generally made to elevate mucosa towards the nasal spine which is very effective in increasing the depth of the vestibule. Subnasal or cheek fullness, obtained by superior push of the intermediate submucosal tissue, satisfies the patient esthetically. A surgical stent, secured with titanium screws, could also be used to cover the operated region (Fig. 19.22).

Secondary epithelialization

Secondary epithelialization is an easy technique to accomplish though rapid and unpredicted relapses often prevent surgeons using this method alone. It could be performed when covering mucosa has an irregular surface and unhealthy status, such as presence of inflamed, granulation, ulcerative, and exophytic soft tissue lesions. The lesions could be removed several weeks before or at the same time as the secondary epithelialization vestibuloplasty.⁴ Secondary epithelialization was described by Kazanjian in 1935⁶ and Clark in 1953.⁵²

A crestal incision is made at the junction of the free and attached mucosa and dissection is deepened to the desired level. The muscle and submucous fat are dissected with scissors. The suprapariosteal surface should be cleansed as much as possible to prevent formation of reactive aberrant granulation in the early healing period (Fig. 19.23). The mucosal flap is sutured down to the junction of the newly formed sulcus and the periosteum. A surgical stent lined with a tissue conditioner could be modified in order to prevent direct pressure of the stent over the raw periosteal surface. Actually, the Clark's technique is preferred to Kazanjian's sulcoplasty since the raw periosteal surface in the latter results in more contracture.

Lowering of mouth floor

As the alveolar bone is resorbed, the attachments of the mylohyoid and genioglossus muscles may interfere with the lingual aspect of the denture causing an inadequate depth for prosthesis. Lowering the mouth floor can be done separately for each anterior and posterior region; however the lingual sulcus also could be deepened at once. This is no longer a recommended procedure.

Anterior lowering of mouth floor

The superficial and lateral fibers of genioglossal muscle are dissected from the genial tubercle and secured via percutaneous sutures to the submental skin fold or labial vestibule.

Fig. 19.23 (a) Preoperative intraoral view of a patient with a wide epulis fissuratum and shallow vestibular sulcus. (b) Ten days postoperative. The healing occurs by secondary epithelialization.

Posterior lowering of mouth floor

Procedures lowering the mouth floor were described by Trauner, Obwegeser, and Macintosh. The mandibular body should be at least 15mm in height. The main objective is to eliminate the rising effect of the mylohyoid muscle on the lingual flange. An incision is made at lingual sulcus parallel to the alveolar wall. Supraperiosteal dissection is progressed to the mylohyoid ridge and the mylohyoid muscle is separated. After the buccal flap is prepared, lingual and buccal flaps are secured with a Reverdin needle at the buccal side. If only lowering of mouth floor is performed, the flaps are anchored to a new lingual sulcus with non-resorbable percutaneous sutures at the skin crease of submandibular region. The periosteal surface is grafted with split-thickness skin or palatal grafts which are protected with a surgical stent.

Such a major procedure in geriatric patients is no longer recommended in the current practice of oral and maxillofacial surgery. Contemporary management of edentulous patients covers dental implant surgery with various prosthetic solutions. These options are more reasonable and effective for solving retention problems in extensively resorbed lower jaws.

Adjunctive and supportive surgical techniques

With the intense use of implants, bony augmentation and reconstructive soft tissue techniques have improved. Instead of simple functional rehabilitation, full esthetic and functional requirements of the patient are met by trying to return to the original quality and quantity of bone and soft tissues. In order to succeed in bone augmentation, there should be sufficient soft tissue to cover the new bone and the implant should be supported by at least 3mm of attached keratinized gingiva. That is why careful handling and management of the soft tissues during surgery determines the final outcome of the whole procedure.

Socket preservation

Micro or macro fractures occurring during dental extraction are avoided as much as possible when the alveolar socket is to be preserved following tooth removal. Conventional extraction methods may be traumatic and cause alveolar bone destruction in the healing period. In order to avoid postextraction bone and soft tissue loss, tooth removal may be performed by periosteal (Fig. 19.24). This tiny and sharp instrument helps to cut the periodontal ligament and forces the roots to the surface. The use of this method enables the practitioner to insert an implant at the same time as tooth removal, as the socket is not widened and/or fractured by conventional extraction methods.

Immediate implant insertion at the time of tooth removal was thought to be a socket preservation

Fig. 19.24 Socket preservation. (a) Removal of the maxillary first molar by periosteal. (b) Immediate implant insertion.

method until recently. However, today it has been shown that bone resorption continues even after immediate implant insertion. Other methods such as filling the extraction socket with biomaterials and covering with membrane are not very commonly used techniques as they are expensive and results are not always satisfactory.

Other well known methods to preserve the socket are removal of roots after separating them by burs or removal of the roots following drilling the roots from inside, starting from the pulp chamber.

If a periodontally compromised tooth is removed, resultant alveolar width and height are mostly less than ideal for esthetic and functional reconstruction. If the residual defect is mild there are a few options to manage this problem; one of them is orthodontic tooth eruption, and the other one is tooth removal followed by alveolar guided bone regeneration (GBR) and/or augmentation.^{23,58}

Orthodontic tooth eruption

Orthodontic tooth movement is a technique that improves the dimensions of hard and soft tissues surrounding periodontally compromised teeth.^{59,60} This technique, also known as forced eruption, is a non-surgical treatment option that facilitates hard and soft tissue remodeling.⁶¹ Bone volume is increased due to the tension applied to the periodontal ligament by orthodontic forces. New bone is deposited by osteoblastic activity where the periodontal attachment

exists. The coronal shift of the tooth causes migration of the soft tissue and the bone in the direction of the movement.⁶¹ Orthodontic tooth eruption is also used to potentiate bone development at the implant site.^{62,63} Although it is a long-term therapy, forced eruption can result in surgical augmentation procedures being avoided.

First teeth should be treated endodontically and filled with calcium hydroxide-based root canal sealer. Direct bonding tubes are then bonded further gingivally, and occlusal reduction is performed to allow extrusion of those teeth. The patient should be examined every 2 weeks to monitor progress and to reduce the occlusal surface of the teeth being extruded.

Implant site development using forced eruption is an alternative technique that provides hard and soft tissue improvement.⁶⁴

Guided bone regeneration

GBR with or without bone graft substitutes is a very well known and commonly applied technique for periodontal defect repair and for mild alveolar defects. Although results are mostly favorable, volume gained by guided tissue regeneration is limited and the high cost of membrane and bone substitutes is another disadvantage.

Ridge splitting

Ridge splitting is another option for augmentation of horizontal defects, especially used in triangular, V-shaped crests with adequate length.⁶⁵ However U-shaped crests cannot be reconstructed by this technique.⁶⁶

Bone grafting

Onlay bone grafts are well protected since grafts are not disturbed with postoperative dehiscences and infection. In moderate defects bone grafting is the widely applied technique for ridge reconstruction. Intraoral bone grafts harvested from the ramus and chin area are closer to the operation area and have low morbidity. Additionally membranous bone grafts may be preferred because they have less resorption than endochondral bone grafts due to early revascularization, better potential for incorporation in the maxillofacial region because of a biochemical similarity, and greater inductive capacity because of a higher concentration of bone morphogenic proteins and growth factors. Cortical bone grafts maintain their volumes significantly better than cancellous bone grafts.

The mandibular ramus and chin are the most favorable donor sites.⁶⁷ Larger amounts of bone volume could be obtained from the ramus area and with less complications. Numb incisors and gum, donor site morbidity, and dehiscence are the main compli-

cations reported after symphysis graft harvesting. Augmentation of alveolar deficiencies both with autogenous bone grafts and alveolar distraction osteogenesis (ADO) are the most frequently used techniques in moderate defects.⁶⁷ However, despite various publications reporting favorable results of these two methods, controversies still exist about the ideal treatment modality. ADO offers significantly better results when the quantity and quality of new alveolar soft tissue are considered.⁶⁸

Alveolar distraction osteogenesis

In larger defects, ADO is an alternative treatment for bone and soft tissue reconstruction.^{69,70} This process is based on the concept of bone distraction along a vector that is transverse to the long axis of the bone, which results in bone formation.^{69,70} It was later applied to the human mandible, and more recent clinical reports have shown that ADO is effective for treating severe forms of alveolar ridge atrophy.⁶⁹ A primary advantage of distraction osteogenesis is that there is no need for additional surgery at the donor site. Another benefit is the coordinated lengthening of the bone and associated soft tissues.^{70,71}

In all these techniques (forced eruption, GBR, bone grafting, ADO, and ridge splitting) the bony volume is increased. In order to obtain successful results both hard and soft tissues should be lengthened and widened. However if open techniques are used, the vestibular depth is lowered and the amount of attached and keratinized gingiva is diminished. The defective alveolus mostly remains uncovered with deficient soft tissue pedicle which is also handicapped with anatomical landmarks limiting the extension of flaps. This may result in tension on the soft tissues during closure and may end with dehiscence and graft, bone substitute, and membrane removal. ADO is the best technique for soft tissue lengthening in a defective alveolus. Especially in moderate and severe defects, this technique enables restoration of soft tissues with desired quality and volume (Fig. 19.25).

Lasers in preprosthetic surgery

LASER is an acronym for light amplification of stimulated emission of radiation. Laser application in maxillofacial surgery practice covers control of leukoplakia, oral malignancy, preprosthetic or periodontal surgery, temporomandibular joint, uvulopalatotomy, and cosmetic procedures.

Clinical lasers are of two types; soft lasers are essentially an aid to healing with relatively few rigorous studies available to support their use. Surgical hard lasers, however, can cut both hard and soft tissues and replace the scalpel and drill in many areas. From initial experiments with the ruby laser most clinicians are using argon, CO₂ and now Nd:YAG

Fig. 19.25 Pre- and postoperative alveolar distraction osteogenesis of the anterior mandible. Note the significant augmentation of the defective mandible. Combination of bone grafts and membranes in similar cases would not provide the same outcome due to difficulty of obtaining soft tissue flap closure. Note that besides bone lengthening, the soft tissues are also lengthened with healthy keratinized and attached gingiva over the alveolar crest.

systems. Both the CO₂ and Nd:YAG lasers can be used for intraoral soft tissue surgeries.⁷²

The advantages of lasers include a relatively bloodless surgical and postsurgical course, minimal swelling and scarring, coagulation, vaporization, and cutting, minimal or no suturing, reduction in surgical time, and, in a majority of cases, much less or no post-surgical pain.

CO₂ laser

Since its development in the early 1960s, the CO₂ laser has been rapidly introduced into medical research and almost every dental and medical surgical specialty. In dental surgery it is mainly used for oral soft tissue applications. CO₂ laser light can be focused for cutting purposes or defocused to secure hemostasis. This laser can also be used to vaporize neoplasms.⁷³

The CO₂ laser offers the dental surgeon an improved alternative to the scalpel due to the advantages of relatively bloodless surgery, decreased postoperative discomfort, minimal swelling and scarring, and the laser's ability to coagulate, vaporize, or cut.⁷⁴ The laser tip does not touch the tissue, thus good access and visibility are obtained. As the CO₂ laser eliminates bleeding, placing sutures is unnecessary. In comparison with traditional electric scalpel, resective operations done with CO₂ laser are 10 times more precise.

The basic surgical procedures that can be completed efficiently with CO₂ laser radiation include:⁷³

- biopsy – tissue cutting and removal;
- removal of mild and early lesions: fibroma, papilloma, coccus, nicotine stomatitis, Wilson's lichen, erosion lichen, epulis, common warts;
- removal of malignant lesions;
- removal of excessive keratosis;
- frenectomy: along lips (along maxilla middle line); along tongue (ankyloglossia);
- gingivectomy, removal of hypertrophies (e.g. caused by dilantin, procordica, ciclosporin, idiopathic, cardizem);
- gingivoplasty;
- reduction of soft tissue tuberosity;
- operculectomy;

- removal of aphthae;
- improvement of hygienic conditions around crowns and bridges: elimination of 'swollen' lips, irregular lip line, removal of overgrown tissue;
- coagulation in transplant collecting sites;
- removal of vascular lesions: hemangioma, pyogenic granuloma;
- treatment of patients suffering from blood clotting disorders: hemophilia, thrombocytopenia, Sturge-Weber syndrome;
- internal ear vestibule shaping;
- implants, stage II, soft tissue removal.

Nd:YAG laser (neodymium)

The first dental laser based on an Nd:YAG engine provides handpieces of similar size to conventional instrumentation and, being fed by a fiber-optic 'cable', has the flexibility for intraoral use that the CO₂ lasers, widely used in oral surgery, lack.^{72,73} The Nd:YAG was the first laser used for its coagulating effect in surgical procedures in the oral cavity. It is used to excise pathologic lesions or for its sterilizing or sealing effect at lower irradiation doses. Since its absorption is 10000 times slower than Er:YAG it cannot be used for hard tissue procedures. The Nd:YAG laser is absorbed by hemoglobin and chromophores (melanin and other proteins). A photothermal effect occurs; after absorption of the laser radiation it is converted to heat, resulting in vaporization and tissue ablation.

The main advantages of Nd:YAG laser application in dentistry are: (1) dry operation field; (2) satisfactory results of postoperative treatment; (3) low invasiveness; (4) high precision; (5) procedure safety; (6) lower susceptibility to caries; (7) convenience for patients.

Parameters for Nd:YAG laser surgery could be chosen as follows:

- Implant release after surgery: power 2.5W, frequency 20Hz.
- Reduction of bleeding: power 3–5W, frequency 50Hz.
- Removal of fibroma/hyperplasia: power 2W, frequency 30Hz.
- Gingivectomy: power 3–8W, frequency 50Hz.

Er:YAG soft tissue surgery (erbium)

With a special surgical handpiece, the Er:YAG laser could also be used conveniently in oral surgery (Fig. 19.26). Frenectomy, gingivectomy, and treatment of stomatitis could be accomplished. Small and deep cuts are observed when a procedure is performed by Er:YAG irradiation. Shallow and wider cuts are obtained with defocused irradiation. Wound healing with minimal damage zone without carbonization takes a week. In small lesions, local anesthesia is usually not required. The treatment parameters are:

- Energy: 50–350 mJ.
- Frequency: 20–30 Hz.
- Pulse width: VSP (very short pulse), LP (long pulse).

Fibromas in the oral region could also be easily treated with Er:YAG laser ablation. The procedure is the same described for soft tissue procedures; however energy requirement differs and should be adjusted to 200 mJ with LP pulse width.

Removal of superficial oral lesions (leukoplakia, lichen planus, keratosis)

Er:YAG is an ideal laser type for ablation of white lesions on the buccal mucosa, palate, and mouth floor, since underlying tissue is not damaged. The lesion is peeled layer by layer like an onion to the required depth. Most cases need two or three appointments after which ablated lesions do not recur even after years.

- Energy: 800 mJ.
- Frequency: 8–10 Hz.
- Pulse width: SP (short pulse).

Emerging technology and the future

Tissue engineering, the science of growing living human tissue for transplantation, opens new perspectives in medical care and will have a positive influence in the field of preprosthetic surgery. Cell culture technology, originally described for cultured skin and mucosal grafts, has opened a new era in the field of oral reconstructive surgery.⁷⁵ The major advantage of cell culture is the expansion of a small biopsy specimen into transplantable mucosal tissue by two to three orders of magnitude within a few weeks. Oral mucosa substitutes are classified into three types:

1. Sheets of cultured autologous keratinocytes.
2. An artificial dermis composed of collagen and/or glycosaminoglycans.
3. A composite oral mucosa, containing both an epithelial and dermal layer.⁷⁶

De Luca transplanted cultured palatal mucosa to replace gingival mucosa and demonstrated that 4 months later the grafts had formed a well differentiated keratinizing mucosa similar to palatal mucosa *in situ*.⁷⁷ Cultured autografts were successfully used instead of split-thickness skin grafts to free the tongue after malignant tumor resection.⁷⁶ Although there were good clinical results with the tissue-engineered mucosa grafts in most of the cases,⁷⁸ some wound shrinkage was observed. This phenomenon might occur because cultured mucosa grafts consist of only a thin layer of keratinocytes without any submucosal connective tissue.⁷⁵

Two skin substitute methods have been frequently used in oral and maxillofacial surgery. One is a mucosal epithelial sheet fabricated by the technique developed by Rheinwald⁷⁹ who described a method for

Fig. 19.26 Frenectomy performed with Er:YAG laser and Nd:YAG lasers. (a) Preoperative view of the labial frenum and the papilloma. (b) Frenectomy by Er:YAG surgery. (c) Coagulation of the operative field by Nd:YAG irradiation. (d) Early postoperative healing at day 3. (e) The final result.

serial cultivation of human epidermal keratinocytes. A second skin substitute technique uses a bi-layered artificial dermis that consists of collagen glycosaminoglycan/silastic sheet available at the time of surgery.⁸⁰ Its major disadvantages are difficulty with suturing and its susceptibility to infection.⁸¹ A dermal replacement (Dermagraft) can also be used instead of skin grafting.⁸²

Studies on production of *ex vivo* intraoral skin/mucosal graft gave promising results,⁸³ however the complexity of the procedure, time, and cost are questioned when simple and fast autogenous grafting techniques are possible. Absence of donor site morbidity should be considered as the most advantageous point of *ex vivo* produced grafts.

Chapter 20

Implantology

Lars Rasmusson and Lars Sennerby

This chapter includes basic knowledge of osseointegration with a focus on the dynamics in tissue reactions following implant surgery. Indications and contraindications for implant treatment are discussed as is the importance of clinical research. Primary and secondary stability as well as loading effects on the bone tissue are analyzed and evaluated. The importance of careful maintenance procedures is emphasized. The difference in treating adolescents and children with oral implants is included. Finally the authors include a section on guided implant surgery technique and conclude that long-term clinical data on modern implant systems on the market today have in general shown high survival rates and minimal bone loss around the implants.

Evidence-based oral implant therapy was presented to the dental community in the early 1980s.¹ Foreign materials have, however, long been used to replace missing teeth. For example, subperiosteal and blade implants had been used for some decades when pure titanium screw-shaped implants were introduced by the experimental and clinical work of P-I Brånemark.² Today, the use of osseointegrated oral implants is considered to be standard procedure for the treat-

ment of total and partial edentulism. Long-term clinical data on modern implant systems on the market today have in general shown high survival rates and minimal marginal bone loss around the implants.³ However, critical reviews of the scientific literature have concluded that some, often low-price systems, are not yet sufficiently documented in long-term clinical trials.

One prerequisite for successful anchorage and long-term function of titanium implants is that a sufficient volume of healthy bone is available in order to house adequate numbers and sizes of implants. The density of the bone is also a determinant of implant success, since failure is more common in bone with low mineral content.

Biological principles behind osseointegration

Implant stability and loading considerations

In the early days of implant dentistry, the use of osseointegrated implants always included a healing period of typically 3–6 months from placement to prosthetic treatment.⁴ The formation of direct bone-implant contacts was considered a prerequisite before loading could be commenced (Fig. 20.1). Today, immediate/early loading of dental implants is a clinical reality and numerous clinical studies have demonstrated as good results as those previously reported for two-stage implants.⁵ This has changed the understanding of what factors are important for a successful clinical outcome. In the early days, focus was mainly paid to the osseointegration process *per se*, whilst today a general stability concept is discussed where bone healing is one of several important factors.⁶

The clinical manifestation of a successful dental implant is the absence of mobility. Thus, achievement and maintenance of implant stability are prerequisites for a successful clinical outcome with dental implants.

Fig. 20.1 Light micrograph of an osseointegrated implant, retrieved from the posterior mandible of a patient 6 months after placement. The implant is surrounded by cortical and trabecular bone.

Fig. 20.2 Light micrograph of a clinically retrieved implant showing dense cortical bone in contact with the implant surface and with signs of ongoing remodeling.

The main determinants of implant stability are: (1) the mechanical properties of the bone tissue at the implant site and (2) how well the implant is engaged with that bone tissue.⁷ The first factor is determined by the composition of the bone at the implant site and is influenced by stage of healing, since soft trabecular

Fig. 20.3 Light micrograph of a clinically failed and retrieved implant. The implant is separated from the bone by a layer of fibrous scar tissue.

bone seems to be transformed to dense cortical bone near the implant surface. The second factor is influenced by the surgical technique, the design of the implant, and the osseointegration process. Successful healing results in bone formation that reinforces the interface zone and forms bridges and a direct contact between the implant surface and the surrounding bone (Fig. 20.2). Unsuccessful healing results in formation of an interface fibrous scar tissue (Fig. 20.3), which can be caused by infection or mobility of the implant after installation.

However, a clinically stable and successful implant also shows a certain degree of mobility on the micro-scale when a load is applied. For instance, if applying a lateral load (bending) to an implant in bone, the implant will be displaced but will return to its original position as soon as the load is removed (Fig. 20.4). Thus, a stable implant can display different degrees of stability, i.e. different degrees of displacement or resistance to load, depending on factors relating to the bone, the surgical technique, and the implant design. During clinical function, loading will be applied in axial, lateral, and rotational directions (Fig. 20.5). Furthermore, axial loads can be in push-in or pull-out directions. Lateral loads can principally be applied from any direction 360° around the implant. Rotational loading can either be clockwise or anticlockwise. Thus, the outcome of implant stability analysis depends greatly on the type of test used and in which direction the load is applied. In essence, stability measurements in bending give information about the stiffness of the implant–bone system, while

Fig. 20.4 Schematic showing displacement of an osseointegrated implant in the bone bed due to application of a lateral load.

Fig. 20.5 An implant is subjected to loads in axial, lateral, and rotational directions.

application of shear forces, with for instance a reverse torque test, measures the strength of the interface. This means that a newly placed implant can show a high degree of lateral stability but is easily removed when applying reverse torque since bone has not been formed and interlocked with the implant surface. With time, bone formation will lead to an increased interlocking with the implant surface and an increased strength of the interface, whilst the lateral stability may be unaffected. Since most implants will be connected with a framework, reverse torque tests are probably less relevant than measurements of lateral stability.

Primary stability

Implant stability is the result of contact between the implant surface and surrounding bone tissue. The degree of primary stability after installation depends on factors related to the bone, surgical technique, and implant design. The biomechanical properties of bone are determined by the ratio of cortical and trabecular bone at an implant site. Cortical bone is built up of densely packed mineralized lamellae, whilst trabecular bone is porous in structure and contains more soft tissue components than mineralized tissue (Fig. 20.6). For this reason cortical bone is 10–20 times stiffer than trabecular bone and provides a better support for an implant. The surgical technique can influence implant stability depending on the choice of drill diameters, depth of preparation, and whether pretapping is used or not. The implant itself also has impact on stability depending on its geometrical features. In a human cadaver study, it was demonstrated that bone density and implant design are important factors that influence primary stability as measured by resonance frequency analysis.⁸ They also found that 1° tapering of an implant dramatically increased the primary stability in poor bone. In continuing work, it was shown that primary stability also is influenced by drill diam-

(a)

(b)

Fig. 20.6 (a) Schematic of trabecular bone. One unit of trabecular bone tissue is mineralized to 40–60%. (b) Schematic showing cortical bone. One unit of cortical bone tissue is mineralized to 90–95%.

eter and whether pretapping is used or not.⁹ In essence, thinner drill diameters, omitting pretapping, and the use of a tapered implant will result in higher primary stability.

Secondary stability

After implant placement the bone tissue will respond to the surgical trauma, which with time results in: (1) a change of the cortical/trabecular bone ratio and (2) an increasing degree of bone–implant contact. The time needed for completion of bone formation and remodeling is in the range of 12–18 months. The impact of the degree of bone–implant contact for secondary implant stability is not known in detail, although it is generally anticipated that more bone contact means better implant stability. However, the change of the trabecular network into a more cortical bone in relation to the implant surface is probably more important. This means that the biomechanical properties of trabecular bone improve with time which leads to greater stability of the implant

(Fig. 20.7).¹⁰ Cortical bone already has favorable properties from an implant stability point of view. Therefore, histological changes of cortical bone will not necessarily lead to an increase in secondary stability (Fig. 20.8).¹¹

The time needed to achieve sufficient implant stability greatly depends on the density of the bone and thereby the primary stability, i.e. an implant with low primary stability needs a long period of healing whilst an implant with high stability needs only short or no healing. The host's ability to maintain and to increase the primary implant stability is also determined by the healing and remodeling capacity, which in turn is influenced by endogenous and exogenous factors such as health, the use of drugs, smoking, irradiation, etc.¹²

Maintenance of stability

When a crown/bridge or an overdenture has been connected to the implants, the conveyed loads and stresses will have an influence on the bone physiolo-

Fig. 20.7 Series of light micrographs showing the implant–trabecular bone interface during healing. The initially slender bone trabeculae forms direct contacts with the implant surface. Continuous apposition of bone results in an increased density of the peri-implant bone.

Fig. 20.8 Series of light micrographs showing the implant–cortical bone interface during healing. Apart from bone formation and fill of the voids at the interface, no major changes of the peri-implant bone density can be seen.

gy. In the early phase, the implant–bone system will be loaded while bone formation and remodeling induced by the surgical placement are still ongoing. It is reasonable to suggest that the bone tissue is more sensitive at this stage than after completed healing as most failures occur during the first year of loading. If the loads are excessive there is an obvious risk that this may lead to resorption, decrease of stability, and eventual loss of the implant. If the loads are within physiological limits it is probable that loading may stimulate further remodeling and adaptation of the bone to the present load situation. Overload has to be looked upon as a relative parameter since this describes an imbalance between loads and the degree of implant stability. In other words, for a given load the overload threshold is lower for an implant with low stability than for one with high stability.

Bone tissue responses to implants

The bone healing process around a dental implant resembles that of normal bone healing.¹³ The surgical trauma created during the insertion of an implant initiates an immediate and preprogrammed healing response at the bone–implant interface. This process involves the formation of a blood clot containing erythrocytes and biologically potent cells such as leukocytes and trombocytes. Cytokines and factors from these cells, the coagulation process, and injured tissues act as chemotactic stimuli on leukocytes and other cell types. The fibrin network within the blood clot provides an important scaffold for migrating cells involved in the formation of new tissues, such as vessels, extracellular matrix, and bone. Mesenchymal cells in the granulation tissue will differentiate to pre-

osteoblasts and subsequently osteoblasts and start to produce immature woven bone (Fig. 20.9). As will be described below, if a certain surface topography is present, new bone formation will occur directly at the implant surface (Fig. 20.10). Bone formation is also seen at the pre-existing bone surfaces facing the implant, probably as a result of activation of so-called resting cells and by populations of newly differentiated stem cells (Fig. 20.11). With time the new bone from adjacent bone surfaces will reach the implant surface and create bone–implant contacts and fuse with the bone initially formed in the granulation tissue near or at the implant surface. A rapid increase of new bone area and degree of bone–implant contact is seen during the early healing period (Fig. 20.12). Bone regeneration occurs in two stages and this is also the case around dental implants. The immature woven bone is replaced by mature lamellar bone through a

remodeling process. This is done by bone metabolizing units (BMUs), which contain osteoclasts, which resorb the woven bone, followed by a seam of osteoblasts, which lay down new layers of bone (Fig. 20.13). It is anticipated that the early bone formation takes about 3–4 months, whilst the remodeling process of the repair may take another 9–12 months in humans. However, physiological remodeling is a continuous process since it is part of the calcium metabolism system (Fig. 20.14).

The majority of early studies on implant integration used machined, minimally rough implants. Today, it is well known that implants with increased surface roughness can result in more rapid integration, with more bone contacts at an earlier stage as a result. Moreover, it seems likely the pathways of implant integration may be different for different surfaces and terms like “contact” and “distance”

Fig. 20.9 Light micrograph showing osteoblasts producing woven bone in a loose connective tissue near an implant surface 7 days after surgery in the rabbit tibia.

Fig. 20.14 Light micrograph of an implant that had been in clinical function for 9 months. Note the formation of secondary osteons indicating ongoing remodeling.

osteogenesis have been coined to distinguish between the two modes of implant integration.^{14,15} Contact osteogenesis means that the implant is integrated by formation of bone directly to the implant surface and distance osteogenesis means that bone is formed from pre-existing bone surfaces towards the implant sur-

Fig. 20.15 Light micrographs demonstrating differences between a minimally rough and a moderately rough implant surface after 7 days of healing in the rabbit tibia. (a) Bone is formed at a distance from the turned and smoother surface. (b) Bone is formed at and along the surface of a moderately rough implant.

face. The differences between contact and distance osteogenesis were demonstrated in a kinetic study comparing oxidized and machined implant surfaces in a rabbit model after 7, 14, and 28 days.¹⁶ The surface-modified implants showed bone formation by osteoblasts directly on the surface, whilst bone formation occurred in the granulation tissue at a distance from the machined implant surfaces (Fig. 20.15). This may be because the initial blood clot retains better to the rough implant surface. The clot can then serve as a scaffold / matrix for migration of mesenchymal cells to the interface. At a smooth implant surface, shrinkage of the blood clot, which occurs after some time, will result in a gap at the implant interface (Fig. 20.16a), whereas the interface is maintained at a rough surface (Fig. 20.16b). Using the microimplant technique, Ivanoff and co-workers¹⁷ demonstrated more bone-implant contacts as well as more bone in the threads of implants modified by blasting or by anodic oxidation compared with machined controls. They observed bone formation at and along the surface of the modified implants whilst the machined implants seemed to be integrated by bone formed from the surround-

Fig. 20.16 Close-up of Fig. 20.15a, b. (a) Distance osteogenesis near a turned implant. (b) Contact osteogenesis at a moderately rough surface.

ing pre-existing bone walls. However, in spite of the biological benefits with surface-modified implants, randomized clinical studies with up to 5 years of follow-up have demonstrated no differences in normal patient populations.^{18,19} Having said this, the experiences with surface-modified implants in more challenging situations, such as bone grafting and immediate loading, indicate superior outcomes with surface-modified implants. The failure rate with machined implants in reconstructive cases was reported to be around 8%.²⁰ The same research group's experiences from the first 200 surface-modified implants, including varying reconstruction techniques, showed a failure rate of 0.5%.²¹ The results indicate that in biologically challenging situations surface modification may make a difference. Similar experiences have been noted when applying an immediate loading protocol, which is another example of a biologically challenging situation. Glauser and co-workers²² reported a failure rate of 17.3% for immediately loaded machined implants and only 3% for oxidized implants.²³ The histology of clinical oxidized implants, retrieved after 5–9 months of immediate or early (2 months of healing prior to loading) loading showed high degrees of integration.²⁴ Formation of bone directly at the implant surface (i.e. contact osteogenesis) could be demonstrated.

Fig. 20.17 Light micrograph of a clinically retrieved implant with mucosa penetrating abutment. The morphology of the implant–soft tissue interface resembles that of teeth.

The contact osteogenesis properties may have a significant impact on clinical results in terms of the integration of implants in situations where primary bone contacts are missing. The placement of implants in extraction sockets is one example of such a clinical situation. A study in dogs comparing the integration of machined and oxidized implants in bone defects demonstrated a more marked and rapid increase in stability for the latter as measured with resonance frequency analysis (RFA) after 4 and 12 weeks of healing.²⁵ The histological evaluation also revealed differences in favor of the surface-modified implants, since more bone was in contact with the oxidized titanium after 4 and 12 weeks.

The marginal tissues

The soft tissue barrier around an implant or abutment is important for maintenance of implant stability and long-term clinical function, since it protects the integrity of the bone–implant interface (Fig. 20.17). The morphology of the barrier resembles that of gingiva around teeth and contains a sulcus epithelium, a contact epithelium followed by a zone of connective tissue down to the marginal bone.²⁶ The presence of capillaries and postcapillary venules suggests that an effective defense mechanism is at hand as inflammatory cells can migrate into the interface for phagocytosis of bacteria and other foreign bodies. One major difference compared with gingiva is the direction of the collagen fibers which seem to run parallel with the implant/abutment surface, while perpendicular fibers are also present at teeth.

Some loss of marginal bone is expected during the lifetime of an implant. Studies have shown that the major changes, about 0.5–1.5 mm bone loss, occur during healing and the first year of loading.²⁷ The reasons are not well understood, but the initial bone

loss is probably related to healing and remodeling of the marginal bone following implant and abutment surgery as well as a response to loading. Mainly based on experimental dog studies, it has been proposed that a submucosal implant–abutment junction results in a micro-gap where microorganisms may be trapped and induce an inflammatory reaction and bone loss. However, follow-up studies have reported similar amounts of marginal bone loss around one-piece and two-piece implant systems, and thus do not support the earlier findings. Moreover, it is generally anticipated that surface roughness and geometric features such as micro-threads at the neck of the implant may minimize marginal bone loss. However, at present the results from clinical follow-up studies are not conclusive on this point. In general, well documented implant systems show minimal average bone loss over time. Having said this, some implants can show extensive marginal bone loss, with or without signs of infection. The incidence and causes of peri-implant bone loss are not well known and are under debate.²⁸

Implant components

Implant components are illustrated in Fig. 20.18:

- implant fixture;
- cover screw;
- abutments.

Indications for implant treatment

The indications for bone-anchored fixed or removable prostheses are edentulism, partial edentulism, and single tooth loss. In other words, any type of tooth loss is an indication for implant treatment, but

Fig. 20.18 (a) Cross-section of fixture and cover screw. (b) Cross-section of fixture and abutment + bridge screw for screw-retained construction. (c) Abutment in zirconium for a cement-retained crown.

it is certainly not the only or even the best solution for all patients. The clinician should always consider the individual situation for each patient and present different prosthetic alternatives together with treatment plans and estimations of costs. The overall goal with implant treatment is to achieve a long-term successfully stable construction. Criteria for successful outcomes with implant-supported prostheses have been proposed.²⁹ Implant therapy is prescribed to resolve prosthetic problems and such prostheses should meet the clinically evolved standards of function, comfort, and esthetics. The prostheses should also allow for routine maintenance and should permit planned or unplanned revisions of the existing design. Treatment outcome success criteria for implant-supported prostheses should also be assessed in context of time-dependent considerations for any required retreatment. The success criteria comprise the following determinants:

1. The resultant implant support does not preclude the placement of a planned functional and esthetic prostheses that is satisfactory to both patient and clinician.
2. There is no pain, discomfort, altered sensation or infection attributable to the implants.
3. Individual unattached implants are immobile when tested clinically.
4. The mean vertical bone loss is less than 0.2mm annually following the first year of function.

Contraindications

Medical contraindications

The absolute contraindications to implant treatment are few but similar to those for all other types of surgeries. As with any surgical intervention, the implant patient should be assessed preoperatively to evaluate his or her ability to tolerate the treatment. Absolute contraindications to implant surgery are limited to acute illness, terminal illness, uncontrolled metabolic disease, and severe bleeding disorders.

Systemic risk factors

Systemic or general risk factors such as age, smoking, and osteoporosis have been suspected to influence the treatment outcome. Follow-up studies have failed to detect any differences between patients under and over 60 years. Even the age group over 80 years showed high implant survival rates.^{30–32} It has been anticipated that osteoporosis/osteopenia may be a risk factor for implant failure, but a few clinical studies and several case reports have demonstrated successful clinical results in patients with diagnosed osteoporosis.^{33,34} So-called dual energy X-ray absorptiometry (DEXA) measurements have been used to assess the degree of demineralization of the skeleton

and it seems that there is little correlation between the bone quality in the jaws and other parts of the skeleton. It has therefore been suggested that the local bone quality as classified during implant placement is the best predictor for implant failure. Interestingly, failure of implants has been reported in patients treated with bisphosphonates due to osteoporosis. There is, however, little evidence yet that oral bisphosphonate medication in relatively low doses increases the risk for implant failure.^{35,36} On the other hand, intravenous administration of bisphosphonates in high doses due to skeletal malignancies may increase the risk of jaw bone osteomyelitis/necrosis. Additionally, the combination of bisphosphonate treatment and corticosteroids may increase the risk for jaw bone disease.

Patients with metabolic diseases are known to have an impaired bone-healing capacity but well balanced diabetic patients have shown a failure rate similar to that of healthy patients.

Studies have indicated that tobacco smoking is associated with poor peri-implant soft tissue health, marginal bone loss, and implant failure. Even though other clinical investigations have demonstrated little or no negative influence on the peri-implant soft tissues and marginal bone level, in general, implant failure is about twice as common in smokers as in non-smokers.³⁷ It is known that smoking has a negative influence on peripheral microcirculation and wound healing and it has been suggested that smoking influences bone quality, which in turn may lead to higher failure rate.

It has been suggested that ongoing chemotherapy could increase the risk for implant failure. Recent studies have not confirmed that, but of course ongoing treatment with chemotherapy should be considered as a risk factor.^{38,39}

Local contraindications

The primary local contraindication is irradiation to the head–neck region, ongoing and 1–2 years post treatment. There is a high risk of failure if implants are installed in irradiated bone tissue and there is risk of inducing osteoradionecrosis.⁴⁰ Other local contraindications are untreated periodontal disease in residual dentition, periapical lesions at adjacent teeth, other untreated jaw bone infections or cysts, and diseases in the oral mucosa.

Treatment of children and adolescents with oral implants

There are situations when prosthetic rehabilitation of children is needed. Trauma or congenital lack of teeth, such as in cleft patient or children with syndromes, may call for prosthetic treatment. The mouth is important for appearance and self-esteem in the growing individual. Missing teeth should primarily

be replaced by orthodontic spaces closure, composite retained onlay bridges or autotransplantation of teeth. Anchoring elements do not follow skeletal growth in space in the same way as biological teeth and therefore placement of osseointegrated implants is usually not indicated in children. During facial growth, the facial bones are displaced relative to each other and to the cranial base, while their surfaces undergo extensive remodeling. The midface grows generally in a downward and forward direction in relation to the cranial base. The mandible has a V-shaped growth pattern which implies a drift of the lingual and buccal cortical plates.⁴¹ Vertical growth is, to a considerable degree, a result of the development of the alveolar process, which in turn is essentially dependent on the presence of the erupting teeth.⁴² In experimental and clinical studies it has been shown that osseointegrated implants are stationary during growth and do not erupt with adjacent teeth, which subsequently leads to infra-occlusion for the implant-supported crown or bridge.⁴³ Additionally, a fixed prosthesis may impede normal skeletal growth. There are, however, situations when the demands for fixed prosthetic rehabilitation with oral or maxillofacial implants are high. The goal in such cases is not to aim initially at life-long function of the implants and superstructure in the growing patient but to temporarily rehabilitate and accept sequential installation of implants over time, as the maxillofacial anatomy matures.

A more common type of temporary anchorage element in children is the temporary orthodontic implant, which is used as an anchorage for orthodontic forces. This type of implant is pointed, does not require preparation and is inserted without raising a flap. It is inserted in alveolar bone or the palate and is usually not in place more than 12 months. It is simple to remove and local anesthesia is seldom needed at removal.

Treatment planning

Clinical examination

General medical evaluation

As with any surgical intervention, preoperative assessment should be carried out to evaluate the patient's ability to tolerate the procedure. Implant surgery may be associated with certain risks but since it is a relatively atraumatic procedure there are few immediate surgical risks. Absolute contraindications are, as described above, acute and terminal illness, uncontrolled metabolic disease, and severe bleeding disorders.

Oral health status

A thorough clinical examination is mandatory. Visual inspection and palpation of soft tissues and under-

lying bone will usually detect excess tissue and give preliminary information of bone shape and width. Time since tooth extraction and status of any remaining dentition should be taken into consideration. Signs of infection or ongoing periodontal disease are contraindications to implant placement. If immediate installation of an implant is planned, the status of the tooth that is to be extracted should be evaluated. Additionally, prosthetic aspects such as loading conditions, interocclusal distance, extension of the superstructure, and any need for cantilevers should be addressed at this stage. Esthetic demands are usually high in the anterior region and therefore the smile line, lip support, mucosal biotype, intercanine distance, and buccal corridors should be clinically evaluated if implant-supported crowns or bridges are planned in the anterior region. Additionally, a facial analysis should be carried out so that any asymmetry or disharmony of the face is noted.

Jaw relations

The sagittal relation between the jaws changes over time in edentulous patients since bone resorption leads to posterior drift of the maxillary alveolar bone and anterior drift of the crest of the mandible. Subsequently, a class III relation will arise. This is, of course, unfavorable both from a loading point of view and maybe also from esthetic aspects. Bone resorption also tends to make the crests narrower, which is why a transversal registration is also of importance. Correct placement of the implants can, at least to a certain degree, compensate for this. In severe cases of resorption, bone augmentation will be needed prior to or in conjunction with implant placement.

Radiographic examination

A comprehensive clinical examination, as described above, should always precede the radiographic examination, which should be done with techniques resulting in the lowest dose but still presenting all clinically necessary information. Failure to diagnose and treat pathologic conditions around remaining teeth and/or residual jaw bone can seriously compromise the results of implant therapy. Intraoral radiographs are still most common in dental practice and can be recommended if a paralleling technique is used. This way, a preliminary estimate of the vertical dimension of the implant site can be obtained. Panoramic radiographs are often used in the preliminary planning. Pathology in the jaws can usually be detected and available bone height can be assessed in both anterior and posterior regions. The best estimate of height and width, however, is obtained with cross-sectional tomography. This technique gives a higher radiation dose to the patient and should not be performed without a clear indication. There are some guidelines where indications for cross-sectional imag-

ing in implantology have been presented.⁴⁴ These are:

- when minimizing the risk of damage to important anatomical structures;
- to provide more information in cases where there is limited amount of bone height and/or width;
- to improve implant positioning that will optimize biomechanical functional and esthetic results.

Computed tomography (CT) and cone-beam computed tomography (CBCT)

Traditional medical CT scanners are big and expensive and have mostly been used for cranio-maxillofacial trauma surgery and for planning of treatment of malignancies in the head and neck region. CBCT scanners have been available for craniofacial imaging since 1999 in Europe and since 2001 in the US. These scanners use a cone-shaped X-ray beam rather than a conventional linear fan beam to provide images of the structures of the skull and maxillofacial bones. Conventional CT scanners use a single row of solid state detectors paired with a fan-shaped beam to capture the attenuated X-ray. CBCT scanners use a square two-dimensional array of detectors to capture the cone-shaped beam. This means that traditional CT provides a set of consecutive slices of the patient while the CBCT provides a volume of data. Both techniques make it possible to get a three-dimensional (3D) image of the anatomy when software is added to the equipment.

The CBCT scanner is smaller than a traditional CT scanner and the radiation dose is relatively lower, which makes it more popular in dental practice.

Radiographic classification of bone quality

Traditionally, classification of bone quality and sometimes also bone quantity has been registered during implant installation. A scale from 1 to 4 has been used, where 4 is the most demineralized type of bone and gives least mechanical support of the fixture at installation. Today, when tomography is getting more common, this rather subjective system can be replaced by the Hounsfield scale. The bone quality can be shown for each individual implant site (Fig. 20.19).

Hounsfield units:

- D1: >1250 HU;
- D2: 850–1250 HU;
- D3: 350–850 HU;
- D4: 150–350 HU;
- D5: <150 HU.

Model analyses

Model analyses are typically done on plaster casts and can be used for anatomic registration and for evaluation of occlusion and articulation. Implant

Fig. 20.19 Bone quality, Hounsfield scale.

Fig. 20.20 First, the planned position of the implant site is marked with a guide drill. This will provide information about the quality of the marginal bone and is also a start point for the first twist drill.

fixture position can also be planned on the model. Modern software and the use of 3D planning will, however, most likely put the plaster cast in the history books fairly soon.

Surgical procedure

Regardless of the preoperative planning and choice of surgical protocol, treatment includes site preparation and installation of the implant, aiming at good primary stability. Figs 20.20–20.26 provide a general overview of a standard implant site preparation with raised mucoperiosteal flaps.

If teeth have to be removed because they are impossible to use for prosthetic reconstruction, prepare for implant placement using an atraumatic extraction technique. The aim is to reduce unfavorable post-extraction ridge remodeling. Bone grafts and/or resorbable membranes may be used to preserve the ridge during healing, especially in the esthetic zone. Immediate installation of implants after extraction is

Fig. 20.21 Drilling should be in the planned direction to the appropriate depth under profuse irrigation. A secured indicator can be used to facilitate the direction of the subsequent drilling.

Fig. 20.22 Drilling is done stepwise to the planned diameter. Mesial-distal distance minimum 2 mm to adjacent roots and 3–4 mm between implants.

an alternative to a staged treatment protocol but there are some prerequisites that have to be fulfilled:

- Absence of active infection.
- Adequate residual ridge.
- Possibility for primary stability.
- Adjunctive use of bone grafting techniques to correct residual defects may be used, especially if there is a gap of >2 mm between the implant fixture and extraction socket.

Maintenance

Postoperative check-ups are mandatory and the intraoral radiograph is still the gold standard for evaluation of marginal bone level. The requirements for radiographic check-up have changed recently and today an individualized follow-up regimen is advised, which depends on factors such as patient cooperation and marginal bone level changes during the first year post-treatment. Annual radiographs are not recom-

Fig. 20.23 Drilling depth is verified before the implant is inserted.

Fig. 20.25 A two-stage procedure means that cover screws are installed and the flaps are repositioned tightly. This method is used when healing period without loading is needed, e.g. in soft bone or when the primary implant stability is poor.

mended if stable marginal levels have been established during the first 1–2 years of function. As a rule of thumb, radiographic evaluation of implants and surrounding bone should be carried out at delivery of the superstructure and then after 1, 3, 5, and 10 years in function. Clinical examination, including registra-

Fig. 20.26 One-stage procedure. Here, the flaps are sutured around the abutments.

tion of plaque and bleeding at probing around the abutments, should be carried out 3 months after delivery of the superstructure and, if without remarks, annually. Good oral hygiene is mandatory after implant treatment, especially if the patient has a history of periodontitis.

Computer-guided implant treatment

When a patient is considered suitable for implant treatment, computer-guided planning and treatment can be used. Computer-guided implant treatment implies that the patient has to go through a CT scan (or CBCT), preferably with a radiopaque scan prosthesis in place, before the data can be imported into a software planning program. There are several different software programs available on the market. To take full advantage of the concept it is recommended to define from the outset, the type of final restoration, the need for provisional restoration, and what surgical protocol to use. The software (Fig. 20.27) can either be used alone or as a base for manufacturing a surgical guide. If a surgical guide is used, it will be the link between the planning done with the software and the actual surgery. Cylinders in the guide replicate the

Fig. 20.27 Software for computer-guided implant planning.

Fig. 20.28 Surgical guides: bone-supported, tooth-supported, and mucosa-support

plan by guiding the drilling and implant installation in the location and orientation defined by the software. The guide is produced using a biocompatible material, usually using a stereolithography process, and is custom-made for each patient. There are three different guides to be used: bone-supported, mucosa-supported or tooth-supported (Fig. 20.28). The bone-supported guide means that a flap has to be raised and the guide should be relatively stable when placed on the alveolar crest. The tooth-supported guide is also fixed and stabilized by the residual dentition and a flapless technique can be used. The so-called mucosa-supported guide means by definition that the surgery is performed without raising a flap. This type of guide will be difficult to keep stable in position during the preparation and placement of implants, so three to four horizontally inserted, stabilizing pins/screw are used to keep the guide in place. The interest in flapless surgery (also referred to as “minimally invasive surgery”) is increasing, since less postoperative swelling and discomfort have been reported.

Chapter 21

Optimal Implant Placement in the Esthetic Zone by the Use of Guided Bone Regeneration

Christer Dahlin

The biological principles and indications for the use of guided bone regeneration (GBR) are described with specific focus on the esthetic zones in the upper and lower jaws. The efficacy of barrier membranes in conjunction with bone healing and reconstructive therapy is the result of mechanical, cellular, and molecular mechanisms. Basic studies on guided bone regeneration have shown the same sequence of healing occurring as in regular fracture repair. Different kinds of biological membranes, resorbable as well as non-resorbable, are described in the chapter. Clinical results are presented and a section on complications is also included. The author concludes that the underlying bone structure of the alveolar process plays a key role in the overall esthetic appearance.

Biological factors influencing the reconstruction of alveolar bone

An absolute prerequisite for implant treatment is the availability of sufficient alveolar bone to support and retain the endosseous implant.¹ Factors such as infec-

tion, cystic lesions, tooth/alveolar trauma or congenital tooth agenesis cause a reduction of the alveolar ridge dimensions to a varying degree. With the increasing drive for optimal esthetic outcome of implant treatment, restoring both the hard and soft tissue levels is essential (Fig. 21.1).²

Tooth replacement in the anterior maxilla is a demanding treatment, since the absence of, or poor, preoperative planning, or the choice of an inappropriate treatment approach can lead to everything from esthetic shortcomings to real disasters.

Esthetic complications can be related to malpositioned implants and the choice of inappropriate prosthetic components. The most critical factors, however, are the anatomic causes that include bone deficiencies in the horizontal or vertical dimensions, and often a combination of the two. This is not infrequently associated with soft tissue defects of the alveolar ridge. Alveolar atrophy and anatomic alterations will have a negative influence on the proper buccal-palatal position of the implant.^{2,3} Malposition of the implant may have effects on the shape, emergence profile, and interproximal contour.

It is important for the clinician to understand that the anatomic contour of the ridge comprises the soft tissue and the underlying supporting bone tissue in all directions. Hence, the soft tissue contour is heavily influenced by the bone anatomy present.

The concept of the so-called biological width has increased the knowledge and understanding of the interaction between the different tissue types and different biomaterial surfaces.⁴ In brief, the soft tissue demonstrates relatively constant dimensions in thickness; the peri-implant soft tissue thickness is about 3–4 mm. It is slightly thinner on the buccal aspect and more pronounced at the interproximal areas. The soft tissue is also slightly thicker in the anterior maxillary area in contrast to the posterior region of the mandible, which demonstrates the thinnest portion in the oral cavity.

Fig. 21.1 (a) Clinical case demonstrating a trauma at young age and subsequent tooth loss (21). Note the buccal atrophy and concavity (arrow) of the hard and soft tissue. Due to the loss of tissue optimal restoration is not possible from an esthetic point of view. The patient has been temporarily restored with a Maryland bridge while waiting for skeletal growth to be completed. (b) Healing following implant placement and simultaneous GBR procedure. The buccal bone has been augmented with BioOss® and a Bio-Gide® membrane. Note the regained harmony of the contour of the keratinized gingiva of the soft tissue. (c) Ample time should be provided for the soft tissue to mature and stabilize prior to the finalization of the tooth. A combination of a permanent abutment in a biocompatible material and a high-quality temporary crown is provided for at least 2 months. (d) Final restoration of tooth 21 with optimal esthetic result. Note the harmony of the hard and soft tissue in the region providing an ideal emergence profile for the final crown.

Due to the relatively constant dimensions of the soft tissue, it is inevitable that the underlying bone structure of the alveolar process plays a key role in the overall esthetic appearance. This is particularly pronounced in the anterior region of the maxilla. This area is also defined as the esthetic zone.

The resorption pattern of the alveolar process following single or multiple tooth loss has been studied in detail and this knowledge is important in the treatment planning of esthetic implant dentistry.⁵⁻⁷ Frequently, loss of the buccal bone plate (horizontal resorption) is seen in trauma patients (Fig. 21.1a). This is most pronounced during the first 6 months following the injury. Another important anatomic structure to consider is the interproximal crest height since it plays a significant role in maintaining the peri-implant papillae. Today it is well accepted that vertical resorption of more than 5 mm from the top of the bony crest to the contact point reduces the probability of an intact papilla by approximately 75%.³ This is particularly the case in situations with multiple tooth loss.

Today's state-of-the-art esthetic treatment not only involves optimally designed crown and bridge solutions. It also involves restoration of the adjacent tissues (Fig. 21.1). Based on the discussion above, a solid

base needs to be created. Thus, reconstruction and correction of bone defects are needed. Numerous methods have been used in an attempt to overcome this problem. Previously, one of the most common methods involved the harvesting and implantation of fresh autogenous bone grafts. However, this involves an extra surgical site, and the morbidity for the patient following such an event should not be ignored. Numerous different types of bone substitute materials have been developed and recent advances are of great interest.

The materials can be divided into three categories:

- **Allografts.** This group of materials is derived from an individual of the same species and contains no viable cells.⁸ The principles for incorporation of allografts follows the same principles as for fresh autogenous bone grafts but the incorporation process probably proceeds more slowly due to the absence of living cells which are both osteoinductive and responsible for triggering the inflammatory process. Frozen or freeze-dried, mineralized or demineralized bone, demineralized dentin, and antigen-extracted allogenic bone (AAA) are all examples of allograft materials.

Fig. 21.2 Scanning electron microscopy image of the bovine hydroxyapatite (BHA) structure of BioOss® after deproteinization. The crystalline structure of BHA is very similar to that of human bone.

- **Alloplastic grafts.** These are developed and derived synthetically and follow the same principles as for allografts, except that the materials contain no proteins and have osteoconductive properties only.⁹ Hydroxyapatite (HA) is probably the best known material in this family. Bioactive glass ceramic is another member of this family that has been tested and demonstrates active bone formation. Calcium sulfate (plaster of Paris) has also been evaluated as a grafting material.¹⁰ Recently great interest has been shown in tricalciumphosphate (TCP) materials. This material is osteoconductive and has the capability to be slowly resorbed and eventually replaced by new bone.¹¹
- **Xenografts.** A xenogeneic graft is derived from bone tissue originating from various species. In order to avoid an immunologic response and subsequent rejection after implantation, the proteins have to be eliminated. The osteoinductive capacity of the material therefore disappears and this type of graft material only acts as an osteoinductive scaffold. During the last decade a bovine hydroxyapatite (BHA) (Bio-Oss®, Geistlich, Wolhusen, CH) has been developed and widely used in conjunction with implant treatment. It is by far the best documented material available on the market at present. The material is quite similar to human bone in its configuration and is considered to be osteoconductive (Fig. 21.2). However, there is a discussion about whether BHA is resorbable, or is slowly degraded, or is phagocytal or non-resorbable. Recent findings claim that virtually no resorption occurs even after several years.¹² The biological impact of these findings remains to be fully understood. The fact that BHA particles are incorporated into newly regenerated bone could actually be of an advantage in esthetic situations where the material will act as “reinforcement” of the newly formed bone tissue and thereby prevent early resorption of the regenerated bone.

(a)

(b)

Fig. 21.3 (a) Schematic drawing illustrating the principle of guided bone regeneration. Barrier membranes are placed in direct contact with the bone surface thereby protecting the defect from interfering soft tissue cells. A secluded environment is created into which only cells from the adjacent bone can migrate. (b) Illustration showing the principle of an e-PTFE barrier membrane. Note the more open portion in the periphery of the barrier, designed to allow more rapid ingrowth of the soft tissue. This will stabilize the membrane and minimize micro-movements. Also note the more cell-occlusive portion placed over the defect.

The biological principles of guided bone regeneration

Over the last two decades, the development of the technique of guided bone regeneration (GBR) has had a significant impact on esthetic reconstruction in conjunction with implant therapy. This technique involves the use of physical barrier membranes during the healing phase in order to avoid ingrowth of undesired tissue types into a wound area.¹³⁻¹⁷

During the 1980s the principle of guided tissue regeneration (GTR) was developed for regenerating periodontal tissues lost as a result of inflammatory periodontal disease. A series of studies documented the possibility of excluding undesirable cells from populating the wound area by means of membrane barriers. This favors the proliferation of defined tissue cells to produce a desired type of tissue (Fig. 21.3).

The principle of physical sealing of an anatomic site for improved healing of certain tissue types is by no means new. During the mid-1950s attempts were made for neural regeneration by the use of cellulose acetate filters.¹⁸

GBR refers more precisely to the goal of the membrane application than guided tissue regeneration. This concept promotes bone formation by protection

against an invasion of competing, non-osteogenic tissues. To this end, bone defects are tightly covered by a barrier membrane of defined permeability and excellent biocompatibility.

Experimental studies have proven that certain tissues within the body possess the biologic potential for regeneration if the proper environment is provided during healing. The ultimate goal of GBR is to use a temporary device to provide the necessary environment so the body can use its natural healing potential and regenerate lost and absent tissues.

The efficacy of barrier membranes in conjunction with bone healing and reconstructive therapy is probably the result of a combination of different mechanisms – mechanical, cellular, and molecular. Examples of these are:

- prevention of fibroblast mass action;
- prevention of contact inhibition by heterotopic cell interaction;
- exclusion of cell-derived soluble inhibitory factors;
- local concentration of growth stimulatory factors;
- stimulatory properties of the membrane itself.

The basic studies on GBR have shown that the sequence of healing occurring in regular fracture repair follows the same basic pattern that is found in osseous lesions during GBR therapy. Based on the scientific evidence available, it can be stated that certain conditions must be met for new bone formation to be predictably accomplished by GBR:

1. There must be a source of osteogenic cells. Viable bone must be present adjacent to the defect where regeneration is desired.
2. An adequate source of vascularity is essential. This supply originates mostly from the adjacent bone surface (Volkmann's canals and marrow compartment).
3. The wound site must remain mechanically stable during healing.
4. An appropriate space must be created and maintained between the membrane and the parent bone surface.
5. Soft connective tissue cells must be excluded from the space created by the membrane barrier. The structure of the material used must be able to accomplish this.

The general function of a membrane used for GBR therapy is to create an environment that will allow the normal healing process to form bone in a defined region (Fig. 21.3). Hence, the host tissue–biomaterial interaction should not interfere with bone formation and maintenance to a clinically significant degree. Biomaterial chemistry and structure should result in minimal foreign body response. Optimal bone–biomaterial interaction characteristics are also desirable. A GBR membrane that allows close adaptation of

bone tissue will allow more complete fill of the space defined by the membrane and stabilization of the membrane within the overall system.

Tissue integration

The phenomena of ingrowth and surface bonding of tissue to a biomaterial are termed integration. Surface and microstructural characteristics are usually responsible for these events (Fig. 21.4). The clinical benefits of GBR membranes that have the capacity to integrate with surrounding tissues are a result of a more mechanically stable (and therefore predictable) wound healing environment. While tissue integration appears to be necessary for optimal performance of a GBR membrane, chemical and structural properties that encourage tissue integration must be balanced with the overall functional needs for alveolar ridge augmentation (Fig. 21.4).

Membrane design criteria and material selection

The acceptance of membrane-assisted regeneration of osseous lesions in the oral cavity has introduced reconstructive dentistry to new therapeutic procedures and biomaterials. Clinicians are being exposed to an increasing number of membrane materials used, or proposed for use, in GBR. In order to select the best material for a specific clinical indication, it is impera-

Fig. 21.4 (a) The outer surface of the GTAM (Gore-Tex Augmentation Material) is designed to create a barrier to passage of cells and to allow connective tissue attachment. The material is 50% air by volume and 25 μm between nodes. (Scanning electron microscopy image.) (b) The inner surface of the GTAM is designed for connective tissue attachment. It is 30% air by volume and less than 8 μm between nodes. (Scanning electron microscopy image.)

tive to understand the functional requirements demanded of membrane barriers for GBR procedures.

If the only requirement of a membrane material used in GBR were to provide a barrier to the proliferation of fibrous connective tissue, any suitable biocompatible material in the form of a cell-occlusive film could be used in clinical practice. However, a membrane that is used for alveolar ridge augmentation must meet a number of requirements in addition to acting as a passive physical barrier:

1. The membrane must be constructed of acceptable biocompatible material. The interaction between the material and the tissue should not adversely affect the surrounding tissue, the intended healing result, or the overall safety of the patient.
2. The membrane should exhibit suitable occlusive properties to prevent fibrous connective tissue (scar) invasion of the space adjacent to the bone and provide some degree of protection from bacterial invasion should the membrane become exposed to the oral environment (Fig. 21.4b).
3. The membrane must be able to provide a suitable space into which osseous regeneration can occur. Spacemaking provides necessary volume with specific geometry for functional reconstruction.
4. The membrane should be capable of integrating with or attaching to the surrounding tissue. Tissue integration helps to stabilize the healing wound (Fig. 21.4a). It helps to create a "seal" between the bone and the material and prevent fibrous connective tissue leakage into the defect, and retards the migration of epithelium around the material should it become exposed.
5. The membrane must be clinically manageable.

Two different types of membrane are the most commonly used on the market. Non-resorbable, e-PTFE (expanded polytetrafluoroethylene) membrane was the first material to be successfully applied for GBR. The use of this material requires a removal procedure once the healing is completed. Although this material demonstrates superior biological response, the extra steps in clinical handling led to the development of biodegradable membranes such as collagen or synthetic polymers. Furthermore, attempts have also been made using other types of barrier membranes such as lyophilized dura, calvarial bone, and peritoneal tissue. However, the results regarding these latter materials are still somewhat limited in applications related to implant treatment.

Biocompatibility

When discussing the clinical outcome of membrane materials, biocompatibility is a fundamental requirement for acceptable function of any implantable medical device. Although this requirement is often taken for granted, tissue interactions involve many

application-specific factors that are governed by complex mechanisms.

A classical definition of biocompatibility by Williams¹⁹ is "*the state of affairs when a biomaterial exists within a physiological environment, without the material adversely and significantly affecting the body*". This should be interpreted with regard to biomaterial used, the indication, and the environment in which the material is placed and maintained. For example, degradable materials are clearly affected by the environment of the body; however, safe degradation is one of the primary intended functions of this class of biomaterials. Biocompatibility is a relative term. All implanted materials interact with the host tissue to some extent. Biomaterials with dissimilar chemical composition or biomaterials with the same chemical composition but with different macro- and micro-structure will demonstrate different cellular or systemic responses.

Non-resorbable membranes

As previously described, non-resorbable membranes were the first materials successfully used in GBR. The best documented material is e-PTFE (expanded polytetrafluoroethylene) (Gore-Tex Augmentation Material, W.L. Gore & Ass. Inc., Flagstaff, AZ, USA). Originally used in medical applications such as synthetic vascular graft and heart patches, the material has an extensive documentation with regard to tissue response and safety. In the 1990s, barrier membranes with special characteristics for GBR were developed and became commercially available (Fig. 21.4). Substantial experimental and clinical data are available for this type of membrane. The biological response is near to ideal and the e-PTFE membrane is still considered the "gold standard" in membrane technology.²⁰ The material is made up of carbon and fluorine chains strongly bonded to each other. This creates a highly chemically stable and hydrophobic material which is ideal for biocompatible tissue interaction. The material has an open outer structure for early tissue integration and stabilization and an inner portion which is responsible for the occlusive properties of the device (Fig. 21.4).

Biodegradable barrier membranes

Collagen membranes are resorbed by enzymatic degradation, while synthetic polymers are resorbed via degradation into lactic acid and water.

Bio-Gide[®] was the first collagen barrier membrane designed for GBR and is by far the best documented product in the literature. It is made from native, non-cross-linked collagen types I and III and consists of two functional layers. The compact layer is cell occlusive and fulfills barrier function, whilst the porous layer allows tissue integration (Fig. 21.5). The membrane has hydrophilic properties, which enable self-adherence to the bone surface, thus providing easy

Fig. 21.5 Scanning electron microscopy image showing cross-section of a biodegradable Bio-Gide[®] collagen membrane. The double layer design is created in order to stabilize the material and prevent soft tissue penetration.

clinical handling. Due to the lack of stiffness, collagen membranes are usually used in combination with bone chips or bone substitutes.

Pure synthetic biodegradable membranes are also available on the market. These materials usually consist of a combination of PLA/PGA (polylactide and polyglycolide). An example of such membranes is RESOLUT (W.L. Gore & Ass. Inc., Flagstaff, AZ, USA).²⁵ Although this demonstrates excellent biological behavior in experimental studies, the amount of clinical data is still somewhat limited.

Indications for GBR treatment

When a defect in the alveolar bone is present, three basic situations can require the use of a regenerative procedure:

- Bucco-palatal bone thickness is reduced, but still allows placement of the implant although with the result of either a dehiscence or fenestration-type defect (simultaneous approach) (Fig. 21.6a).

Fig. 21.6 (a) Buccal concavity in combination with minor vertical bone loss due to earlier trauma. The bone tissue is not sufficient either for optimal implant placement or support of the soft tissue. (b) Buccal mucoperiosteal flap raised. Note the design of the flap including one extra tooth on each side of the implant site. The implant is placed in optimal position according to the preoperative prosthetic planning using a surgical stent. Lack of buccal bone and several exposed threads of the implant are evident. (c) BioOss[®] particles mixed with autogenous bone particles harvested from preparation of the implant site are placed in the defect area and also used to cover the surface of the implant. (d) A Bio-Gide[®] membrane is trimmed and placed over the defect area. Note that the membrane is allowed to extend into the periphery from the graft material. Also note the trimming which leaves approximately 1 mm of space between the membrane and the adjacent root surfaces. (e) Clinical photograph showing uneventful healing after 6 months. Note the harmony of soft tissue contour compared to prior to treatment (Fig. 21.6a). (f) Completion of the treatment. Final crown (Procera[®]) in place. The soft tissue contour including the height of the papillae is evident.

- Horizontal bone thickness is reduced in such a way that optimal implant placement with regard to prosthetic planning is not possible (simultaneous approach).
- Bone thickness is so reduced that implant placement is not possible with proper primary stability. In this situation, ridge augmentation is required prior to implant installation (staged approach).

Basic surgical technique of GBR

Preoperative antibiotics

The same antibiotic prophylaxis is recommended as in conjunction with implant placement according to standard protocol. Usually a 1-day regimen including 2 g fenoxymethyl-Pc $\times$ 2 is enough. For advanced GBR cases, 1 week's antibiotic coverage postoperatively is recommended.

Flap design

A full-thickness crestal incision, slightly buccal but still within attached mucosa, is performed and extended mesially and distally to the adjacent teeth. Diverging releasing incisions are then performed buccally (Fig. 21.6b). Full-thickness mucoperiosteal flaps are elevated.

Site preparation

Based on the available amount of host bone present, simultaneous implant placement can be performed. If optimal position and direction and satisfactory primary stability cannot be obtained, a two-stage procedure should be considered.

The bone surface in the augmentation area should be carefully debrided in order to remove all remnants of soft tissue. If implant placement is performed it should be performed according to the protocol of the implant system used, aiming at a prosthetic-driven position (Fig. 21.6c).

Prior to placement of graft material and the barrier membrane, the buccal bone plate in the defect area must be perforated to create access for multipotent cells and blood vessels emanating from the marrow cavity. This can be performed either with a spiral or a round bur with a dimension of approximately 1 mm. This surgical procedure is believed to stimulate osteogenesis by activating a cascade effect of growth factors. Furthermore it allows the formation of an appropriate coagulum which will act as a matrix for the initial bone formation.

Graft material

The use of spacemaking materials underneath the membrane has been proven to provide a more pre-

dictable regenerative result and is today considered state of the art. Many different materials, including autogenous bone chips, freeze-dried-demineralized, deproteinized bovine bone, and synthetic graft materials such as TCPs, have been tested with varying results. The best documented filling material with predictable outcome is a combination of deproteinized bovine bone (Bio-Oss, Geistlich, Switzerland) and autogenous bone chips mixed in a ratio of 1:1. The addition of Bio-Oss has been shown to minimize resorption of the newly regenerated bone (Fig. 21.6c).

Membrane selection and positioning

The anatomic shape of the defect to be regenerated dictates the choice of membrane material. The following protocols can be recommended.

Biodegradable membranes

Most defects can be treated with resorbable membranes together with autogenous bone chips alone or in combination with bone substitutes. Usually the autogenous bone chips are placed in contact with either the bone surface or the exposed parts of the implant and then covered with a layer of Bio-Oss. Alternatively the two filling materials are mixed together in a ratio of approximately 1:1.

The membrane must be cut and trimmed to adapt to the anatomy of the ridge and applied over the defect in order to cover the bone graft. Due to the hydrophilic properties of the Bio-Gide membrane it will "stick" to the bone surface once wetted either with saline or blood. Hence no fixation screws or tacks are needed for stabilization in most cases (Fig. 21.6d).

Non-resorbable membranes

When a large volume of bone (outside the bone envelope) must be regenerated, the use of non-resorbable e-PTFE membrane is indicated. The preparation of the augmentation site is identical to that described above. However, extra attention must be paid to the membrane adaptation and fixation. The membrane must be cut to extend at least 4–5 mm beyond the filling material to avoid interference with the surrounding soft tissue. It is important to avoid creating sharp edges since they can increase the risk for membrane perforation during healing. A critical note is to trim the membrane so a distance of 1–2 mm is maintained from the root surface of the neighboring teeth. This is to avoid contamination due to bacterial downgrowth along the root and also to enhance periodontal reattachment.

Finally, the membrane should be fixated using either micro-screws or specially designed tacks. It is practical to start this procedure on the palatal side

prior to the placement of the bone graft material (Fig. 21.7). A critical technique is the adjustment of the flaps prior to suturing. A completely tension-free environment must be created by performing periosteal releasing incisions at the base of the buccal flap.

Suturing

Suturing is recommended using non-resorbable sutures in a biocompatible material. A double suture layer should be created with a combination of horizontal mattress sutures (4/0) (on top of the crest) followed by single interrupted sutures (5/0 or 6/0) for mucosal closure.

Follow-up

Due to the compromised wound, the recommendation is to maintain the sutures in place for at least 14 days. The patient should receive systemic antibiotics (amoxicillin) for 5–10 days when they have undergone a more advanced GBR procedure. In addition, the patient should rinse with chlorhexidine solution for 3 weeks after placement of the GBR barrier. This could thereafter be switched to a 1% chlorhexidine gel which is gently applied in the wound area only once daily.

The e-PTFE membranes are removed after 6–8 months (either at the time of fixture installation or abutment connection). During this healing period, the patients are checked once a month for plaque removal and any complications.

Temporary dentures

Implant treatment and related bone augmentative procedures are usually associated with a situation where the patient needs a temporary solution during the respective healing phases. Clinical studies have demonstrated a clear correlation between membrane exposure and pressure from temporary dentures in the wound area. Hence, strict rules apply for the design of the temporary solution in conjunction with GBR. Ideally, fixed solutions such as Maryland bridges or conventional temporary bridges are the first choices if possible. If a temporary removable denture is necessary, it should be designed in such a way that no contact is present between the base of the denture and the soft tissue covering the GBR membrane. Furthermore, occlusal support of the denture is mandatory in order to prevent a pumping pressure when chewing.

Membrane removal

A non-resorbable barrier membrane is removed under local anesthesia. Technically the easiest way to approach the membrane is from the lateral aspect and to dissect it free from the covering soft tissue layer. Following this procedure, it is usually easy to remove the barrier from the underlying bone tissue. Great care should be taken to remove the entire membrane material. This is usually performed in conjunction with either implant placement or abutment connection. Biodegradable barrier membranes do not usu-

Fig. 21.7 (a) Edentulous area in the posterior maxilla. Both horizontal and vertical bone loss are present. Without bone augmentation in conjunction with implant treatment, a less than ideal esthetic outcome regarding the length of the clinical crowns would be evident. (b) Esthetic-driven implant placement. Implants are placed according to prosthetic planning transferred via a surgical stent. Note the level of the present bone in relation to the placement of the fixture heads. A titanium-reinforced GTAM has already been secured palatally by means of titanium fixation tacks. The defect area will subsequently be filled with a mixture of BioOss® and autogenous bone particles. Finally the membrane will be wrapped over the graft buccally and sealed with micro tacks. Suturing is according to the described protocol. (c) Radiograph showing the augmented area after 6 months of healing. Note the newly formed bone between the implants (compared to Fig. 21.7b). The tacks used for membrane fixation are also visible on the radiograph. (d) Clinical photograph after abutment connection and subsequent healing. (e) Final reconstruction: ProCera® crowns placed. Note the optimal length of the clinical crowns that matches the neighboring teeth. (f) Radiological follow-up after 1 year in clinical function. Note the bone height is maintained in between the implants. The bony support allows a stable soft tissue level around the superstructure.

ally require this procedure. Most biodegradable membranes on the market are designed with a resorption pattern of less than 6 months.

Clinical results of GBR

A variety of techniques and materials has been used to establish the structural base of osseous tissue for supporting dental implants. GBR is a surgical concept which has been in clinical use for well over two decades. It has undergone several developments and improvements and is nowadays considered a predictable treatment modality, once the previously described issues have been taken fully into account. Doubts have previously been raised regarding the quality and lasting capability of membrane-regenerated bone when being put into clinical function. Previous experimental studies have clearly shown the positive dynamics of this type of bone over time. Recently this has also been confirmed in several clinical studies. In a recent review study by Aghaloo and Moy,²³ the GBR technique was compared to different types of grafting procedures such as autogenous onlay, veneer (OVG), interpositional inlay grafting (COG), distraction osteogenesis (DO), and ridge splitting (RS). The data originated from a database search which identified 526 articles. Finally 335 articles met the criteria. Implant survival rate was 95.5% for GBR technique, 90.4% for OVG, 94.7% for DO, and 83.8% for COG. Hence GBR technique performed better or equal to more advanced bone grafting procedures using autogenous bone.

Another interesting clinical finding is that it seems slightly easier to augment bone in the maxilla compared to the mandible. The use of provisional restoration during the healing period seems to improve the result. Early implant placement also seems to be preferable if possible, due to alveolar ridge preservation, more favorable defect morphologies, and probably a higher regenerative capacity of the adjacent bone.²¹

Bone augmentation of atrophic jaw bone and, particularly, in the esthetic zone in the maxilla is a delicate and technique-sensitive procedure. The principle of GBR offers an alternative that is less resource demanding and also results in less morbidity for the patients. Predictable results can be obtained if a thorough understanding of the biological principles is applied in the clinical setting (Fig. 21.7).

Chapter 22

Implant Placement in the Posterior Mandible

Bo Rosenquist

This chapter is a comprehensive overview of alternative methods to rehabilitate edentulous areas with compromised bone situations in the posterior lower jaw. The anatomy, with the mandibular canal as a limiting structure, is carefully described. Different methods to solve problems, including short implants, surgical positioning lateral to the nerve bundle, nerve transposition, and nerve lateralization, are described in detail. Alternative surgical methods to improve the bone situation like onlay grafting and distraction osteogenesis are also discussed. The author emphasizes the importance of a careful, skilful surgical technique and includes a section on complications that may arise with this type of surgery.

Anatomy of the posterior edentulous mandible

Normal topography

The curvature of the alveolar process of the mandible is narrower than the body itself; the posterior parts of the alveolar process are positioned much more lin-

gually than the mandibular body. In the second and third molar area the bony substance of the oblique line, running from the coronoid process, is superimposed on the outer alveolar plate because of this divergence of the alveolar process and mandibular body. This gives an impression of a thick alveolar plate. Lingually, the temporal crest from the medial part of the coronoid process follows the course of the oblique line. Behind the third molar these two lines form the retromolar triangle which continues anteriorly as the alveolar crest. To accommodate the comparatively thicker roots of the molars the alveolar crest is wider and the crest flatter in the posterior than in the anterior parts of the mandible. Lingual to the second and third molars the downwards sloping mylohyoid line adds to the thickness of the superior parts of the alveolar crest. Hence, a cross-section of this part of the mandible is angulated lingually.

In the first and second molar area there is a shallow concavity in the lingual surface, the submandibular fossa. Further anteriorly, in the area corresponding to the premolars, the more distinct sublingual fossa is found.

As the oblique line continues anteriorly and inferiorly it gets less pronounced which gives the impression of a thinner mandible. The orifice of the mental canal, the mental foramen, is found in the buccal cortex, between the roots of the first and second molar, usually a couple of millimeters below the apices. As the curvature of the mandible increases in this region, the anterior rim of the orifice is sharper than the posterior.

The mandibular canal

The mandibular neurovascular bundle enters the mandibular canal through the mandibular foramen. This is a wide opening situated approximately in the center of the lingual surface of the mandibular ramus, hidden behind a thin, bony process, the lingula. During the first 8–10 mm the canal runs close to the lingual cortex. As it descends it moves to a more central position in the bone in a smooth curve downward

and forward into the mandibular body some 6–8 mm from the mandibular base. The curvature of the canal is less pronounced as it continues in the mandibular body. This means that the canal runs continuously closer to the mandibular base until it reaches the area between the first and second molar from where it moves upwards to the mental foramen in an increasingly sharp curve. As the canal moves inferiorly it moves lingually and reaches its most lingual position at its most inferior position, between the first and second molar. From there it runs closer to the buccal cortex. When the mandibular canal forks into an incisor canal, containing the anterior plexus of the nerve, and a mental canal (usually called the mental foramen), containing the mental nerve, the canal is positioned approximately 3–4 mm from the buccal surface. What is known as the mental foramen is actually a canal through which the first 2–4 mm of the mental branch of the mandibular nerve run before it leaves the mandibular body apical to, and between, the first and second premolar. However, in a few cases its location may vary from the canine to the first molar.¹ The mental canal usually runs perpendicular to the sagittal cardinal axis of the head. Thus it runs slightly posteriorly to the surface of the mandible after leaving the mandibular canal but the pattern of emergence seems to vary between population groups.² The posterior direction may be readily seen in lateral radiographs and has been interpreted as a loop.^{3–5} The length of the loop has been measured at between 0 and 7.5 mm.^{6–8} However, others have shown that the loop is a radiographic artifact rather than an anatomic structure and that it should have no impact on implant surgery.^{5–7,9} The anterior and posterior walls of the mental canal are frequently not parallel, but converge towards the foramen, which may explain the differ-

ence in findings between radiographs and clinical findings.⁷

As the upwards curve of the mandibular canal is accentuated close to its ramification, the mental canal reaches the mental foramen slightly from below. The incisor canal continues anteriorly after the furcation of the nerve. The size of the canal anterior to the furcation varies considerably; from being the same size as the main canal to a diminutive, almost invisible canal. However, even in cases where the canal is initially rather wide it soon narrows as it runs anteriorly.

The expression "mandibular canal" may give a false impression of a rather robust structure with thick cortical walls. In a few cases this may be true (Fig. 22.1a) but in most cases the walls are fairly thin, in some cases they seem almost non-existent (Fig. 22.1b). Normally the walls of the mandibular canal are perforated by small vessels and nerve fibers leaving the neurovascular bundle to the teeth. It is not known whether these perforations eventually disappear when the vessels and nerve fibers atrophy after teeth have been extracted. The mental canal seems to be usually surrounded by solid cortical walls, which are a continuation of the buccal cortex.

The periosteum that covers the exterior surface of the mandible continues into the mental canal and along the mandibular canal as an endosteum covering the surface of the walls of the canals.

The mandibular neurovascular bundle

The inferior alveolar nerve, sometimes called the mandibular nerve, is the third branch of the fifth cranial nerve, the trigeminal nerve. The mandibular

Fig. 22.1 (a) Cross-section of the mandible. Mandibular canal with a thick cortical wall. (b) Cross-section of the mandible. Mandibular canal with an extremely thin cortical wall.

branch is a sensory, polyfascicular nerve. This means that all information initiated by a stimulus on a specific area of the lip, the mentolabial fold, the chin, the teeth, the alveolar mucosa or the buccal soft tissues close to the mental foramen is transmitted from the periphery via the Gasserian ganglion to the nucleus in the brain by a specific nerve fiber. The nerve fiber is surrounded by a sheath, the endoneurium. Nerve threads from receptors in a certain area and their endoneurium are grouped together and surrounded by a sheath of dense connective tissue with thick collagen fibers, the perineurium, to form fascicles. These fascicles are embedded in loose connective tissue and surrounded by another sheath made up of thick collagen fibers, the epineurium, which constitutes the surface of the nerve. Internal blood supply is delivered by vessels in the loose connective tissue surrounding the fascicles, and external blood supply is from vessels running along the nerve outside, but sometimes integrated in the epineurium. While in the bony mandibular canal, the nerve is surrounded by the endosteum. Along the mandibular canal, dental and interdental terminal branches, the dental branches, enter the teeth and receive information from the pulps while the interdental fibers perforate the interdental septa and supply information from the periodontal ligaments and the gingival papillae.

At the furcation, the dental and mental nerve fascicles are separated into two nerve trunks; the dental fascicles continue anteriorly as the anterior plexus, while the mental fascicles, which were positioned below the dental fascicles in the alveolar nerve, form the mental nerve and leave through the mental canal. At the orifice of the canal, the mental nerve usually appears as two or three branches that are further divided to serve the skin and mucous membrane of the medial and the lateral parts of the lip, and the mucosa of the labial alveolar surface.¹⁰

As the nerve is sensory, damage cannot lead to motor impairment. However, it may result in sensory deficiencies in the whole or parts of the reception area of the nerve, depending on the number of and which specific fascicles have been damaged.

Resorption patterns of the alveolar ridge

As the alveolar crest is wider in the premolar and molar area than in the anterior region, vertical resorption is slower in the posterior parts. On the other hand, molars and premolars are usually lost earlier than incisors. Thus when patients seek implant placement, the posterior regions are usually equally or more resorbed than the anterior.

In the posterior molar area resorption usually results in a wider arch and a wider crest as resorption reaches the oblique and mylohyoid lines. In the first molar and especially in the premolar area, two different resorption patterns are seen, although combina-

tions of the two are common. Whether the resorption mode is due to the angulation of the alveolar crest or genetically determined is not known.

The usual pattern is vertical resorption. This results in a flat and rather wide crest. If the resorption is moderate, leaving more than 10mm height of bone superior to the mandibular canal, implant placement is usually uncomplicated. However, as resorption continues, the height above the mandibular canal is reduced and in advanced cases, where resorption reaches the level of the mandibular canal, the foramen is found on the top of and even slightly lingual to the top of the crest with part of the alveolar nerve positioned under a thin layer of bone or even directly under the alveolar mucosa.

The other, less frequent, resorption pattern is lateral resorption. This results in a narrow crest, in advanced cases in a very high, thin ridge made up of cortical bone which is totally unsuitable for implant placement.

General considerations

Placement of implants posterior to the mental foramen presents problems not usually found in the anterior parts of the mandible. Modern implantology as presented by Brånemark was developed for placement of implants between the mental foramina in totally edentulous mandibles. In this area, the mandible consists of thick buccal and lingual cortical plates with only a narrow space of cancellous bone in between. Implants can thus usually engage and be stabilized by both the buccal and lingual cortical bone as well as the cortex of the base and of the crest. Excellent initial stability is usually obtained.

The situation posterior to the mental foramina is different. The mandibular body is usually wider and the upper, lingual, and buccal lateral cortices are thinner. Thus, stability offered by the upper cortex is often inadequate and in most cases stability cannot be expected from the lingual and/or the buccal cortex as the mandible is too wide. The mandibular neurovascular bundle necessitates the use of shorter implants which cannot be secured in the cortex of the base of the mandible. In addition, the cancellous bone seems to be substantially less dense and varies more in density than is the case between the foramina. Thus, initial stability comparable to that obtained in the anterior region cannot be expected and it follows that the success rate is lower.¹¹

The surgical technique has to be adapted to save the thin upper cortex. Where counter-sinking is part of the procedure this may have to be done very gently so as not to destroy the cortical fit of the implant. In cases where the height of a very thin alveolar crest has to be reduced to allow the placement of implants, the reduction may have to stop short of the width equal to the diameter of the implant or no cortex may be left to stabilize it.

In a clinical situation it is easy to misjudge the inclination of the lingual surface of the mandible. The surgeon has to be aware of the risk of perforating the lingual cortex when drilling the implant seats. Due to the anatomy of the mandible this risk is especially high in the premolar and second/third molar areas. The lingual vessels should normally be positioned halfway between the lingual cortex and the midline of the floor of the mouth but the floor of the mouth is richly vascularized with minor vessels and severe, even fatal, bleeding has been reported after perforations of the lingual cortex.¹²

There is a persistent rumor among surgeons that if you have a very gentle hand when drilling the implant seats you can feel when you reach the roof of the mandibular canal, and that implants may obtain extra stability by being secured into the cortex of the roof of the canal. Any such procedures should be strongly discouraged; the thickness of the roof varies but even in the most extreme cases is not thick enough to bring about any sensation of increased resistance (Fig. 22.1a, b). Another rumor is that if infiltration anesthesia is given to the patient instead of a mandibular block, the surgeon could be warned when drilling close to the canal in the posterior part of the mandible. Again, this is a highly unpredictable procedure not supported by any studies, and is not recommended.

Usually, the molars and premolars are lost before the incisors and canines. After a long period of edentulism in the posterior mandible, extensive alveolar resorption may have occurred. This has two clinical implications; the different levels of the crest make esthetic reconstruction difficult without bone onlays or distraction osteogenesis, while elongation of the antagonists in the maxilla may make these procedures impossible because of lack of intermaxillary space. In extreme cases, elongation of the antagonists may make implant therapy impossible without a segmental osteotomy of the premolar/molar area in the maxilla.

Another difficulty in the posterior part of the mandible should be mentioned. To increase stability of the prosthetic reconstruction, the implants should be placed in the form of a curve. In the incisor region this automatically follows the anatomy of the mandible, but in the posterior area implants will tend to be placed in a straight line. The surgeon should consider alternative techniques to increase stability by varying the positions of the implants.

Implant placement superior to the mandibular canal

Conventional implant placement in the posterior mandible may be associated with the risk of nerve damage.^{13,14} However, as long as the distance between the superior cortex and the mandibular canal is 13 mm or more, implant placement in the posterior mandible is little different from elsewhere if the difficulties

mentioned in the preceding section are observed. The distance between the surface of the alveolar crest and the roof of the mandibular canal can relatively accurately be calculated by means of a panoramic radiograph once the position of the mental foramen has been clinically established. When the distance is less, more accurate measurement becomes imperative. Numerous methods to establish the location of the mandibular canal have been presented.^{15–17} When extreme accuracy is needed, a surgical guide based on a three-dimensional (3-D) model should be made and used during surgery.¹⁸

Nerve damage may occur even if the canal is not directly traumatized during implant surgery. The implant seat is usually drilled 0.5–1 mm deeper than the length of the corresponding implant. When working close to the canal it is tempting to be cautious and drill less deep. This may result in the implant being placed a little deeper than the seat allows, compressing the apical cancellous bone, and, indirectly, the roof of the canal, without the surgeon realizing. This results in pressure on the neurovascular bundle. If the compression is minor, only a part of the sensory area may lose sensation temporarily. A more severe compression may lead to compartment syndrome in the nerve and permanent nerve damage with anesthesia, paresthesia or hyperesthesia. Should the surgeon observe any such symptoms postoperatively, the pressure on the nerve should immediately be eliminated, either by unwinding the implant one or two rounds or by open exploration of the nerve.

The use of wider implants

To compensate for the reduced bone-implant contact area when shorter implants are used, wider implants may be considered. These also have an esthetic advantage in the posterior area; the wider neck of these implants mimics the size of the cervix of the molars. Both the esthetic and functional results may therefore be enhanced.

When using wider implants the surgeon should be aware that with increased diameter the speed at the periphery of the drill and implant are exponentially increased. Gentle drilling and placement of the implant are imperative to avoid failures due to overheating of the bone.

Placement of implants lingual to the neurovascular bundle

To allow the use of longer implants, placement lingual to the mandibular canal has sometimes been recommended. The impression that the implants are placed lingual to the neurovascular bundle and secured into the cortex at the base of the mandible may be given by illustrations such as Fig. 22.2. However, as can be seen in Fig. 22.3, the bone lingual

Fig. 22.2 Nerve transposition has been performed on the right side. As bone chips have been placed between and lateral to the implants the former alveolar canal can no longer be seen across the implants. As the buccal cortex has healed, a new “retromolar” foramen has been formed posterior to the implants on the right side. On the left side a so-called “lingual placement” of the implants has been performed. Note that the canal can still be seen across (buccal to) the implants. A false impression is given that the implants are secured into the base of the mandible but in reality are placed into the floor of the mouth.

Fig. 22.3 Set of cross-sections of a mandible from the mental foramen (upper left) to the third molar area (lower right). The amount of bone available for implant placement lingual to the neurovascular trunk is insufficient.

to the mandibular canal is too thin to allow insertion of implants. To obtain a result as shown in Fig. 22.2 the implants have to be angulated to perforate the lingual cortex immediately above or at the level of the canal and the implants are thus inserted into the floor

Fig. 22.4 Lingual placement of an implant. Note how the implant has been unfavorably angulated to avoid interference with the neurovascular bundle.

of the mouth. This may have the advantage of double cortical anchorage but the method is highly dangerous and may even be life threatening. As has been discussed above, fatal incidents have been reported after accidental perforations into the floor of the mouth. Due to the resilient tissues in the floor of the mouth, bleeding may pass unnoticed until it suddenly manifests itself as an airway obstruction.^{12,19} As the implant seat is drilled without visible or easily calculated reference points, laceration of the neurovascular bundle is also highly probable.

Of course, it may be argued that this technique allows for a bicortical anchorage of the implant, and in a few selected situations this technique may have its place. However if the distance to the mandibular canal is short, the implants have to be angulated in a way that makes it difficult to achieve a satisfactory esthetic and functional prosthetic reconstruction (Fig. 22.4); in cases where the height above the canal is sufficient, a safer choice would be to choose to place a shorter and maybe wider implant above the canal rather than taking the risk of placing it lingual to the nerve bundle.

Crestal split

Sometimes an advanced lateral resorption pattern of the alveolar crest results in a high but very narrow crest unsuitable for implant placement, even if implant perforations both lingually and buccally are accepted. In such cases, the intermaxillary space permitting, a so-called crestal split may be considered.^{20–26} Typically the method is used in the anterior maxilla but it can be adopted for use in the posterior mandible as well. The crest has to have a wide base containing cancellous bone that runs well into the top of the crest and the cortex must not be too thick. In these cases success rates in the range 85–95% have been reported.^{20,21} However, in the posterior mandible very few cases qualify for this procedure. The bone has to be elastic to permit bending or a controlled breaking. Thus the patient has to be young. In most cases the thin crest is made up of a unified lingual and buccal

cortex without any cancellous bone in between. This makes a split highly unpredictable or even impossible. In most cases other methods are to be preferred.

Surgical technique

After an incision has been made along the top of the crest, a lingually based flap is raised (Fig. 22.5). A buccal flap only about 2mm wide is raised, to preserve the blood supply to the buccal cortical plate. A thin groove is drilled along the top of the crest until cancellous bone is reached. A chisel is cautiously driven well into the groove by a mallet while care is taken not to interfere with the neurovascular bundle. The chisel is then gently rotated until the gap widens and, in most cases, a green-stick fracture is produced at the base of the buccal cortex which is nourished by the attached periosteum. If the cortex is thick or only a short length of the crest is involved in the operation, additional vertical cuts may have to be made at both ends. Vertical incisions for these cuts should be placed anterior and posterior to the bony cuts and narrow vertical flaps raised to expose the area planned for the cuts. The implants can then be inserted in the gap. In some cases it is not even necessary to prepare a seat.

Fig. 22.5 Schematic sketch of a crestal split. A groove is made with a fissure bur along the crest into the cancellous bone, and a chisel is gently inserted and twisted until a space wide enough for insertion of the implants is created.

The gap between the implants may either be covered by a membrane and / or the space filled with a particulate bone graft. If the buccal bone has fractured it has to be secured by lag screws into the lingual cortex to provide initial stability for the implants. Soft tissue covering is produced by the lingual flap; this may sometimes be difficult. Second-stage surgery can be performed after 5–6 months.

Onlay augmentation in the posterior mandible

Indications for augmentation of the posterior mandible may be esthetic as well as functional. An esthetic problem is found in cases where the edentulous posterior part of the mandible is resorbed to a level well below the marginal level of the anterior, dentulous area. A residual crest thinner than 4mm or with a residual height above the mandibular canal less than 7–8mm presents a functional problem. In both cases, augmentation could be one of several possible solutions.

Onlay grafts and implant placement can be performed as a one-stage or a two-stage procedure, with autografts, allografts, xenografts, mixtures of these and various bone cements.^{27–30} Block grafts or particulate grafts may be used. At present, autogenous cancellous bone grafts seem to be the “gold standard” against which the merits of other grafts are measured.³¹

Vertical onlay

There are two limitations associated with augmentation of the posterior mandible; the antagonists in the maxilla may have elongated, leaving too little intermaxillary space for a prosthetic reconstruction. As has been discussed earlier, a segmental maxillary osteotomy with superior displacement of the osteotomized segment may be considered in these cases. The other is the problem associated with covering a vertical graft while preserving the depth of the vestibule. The vestibule is usually shallow in the molar area, even more so after alveolar resorption extensive enough to make an onlay graft necessary. When an onlay graft is covered there is a tendency for the ves-

Fig. 22.6 Schematic sketch of a horizontal onlay graft. The depth of the vestibule has been reduced.

tibule to be reduced even further; in extreme cases it can be totally lost leaving the augmented mandible lying in the buccal soft tissues (Fig. 22.6). A second procedure, either a preoperative tissue expansion or a postoperative vestibuloplasty with grafting of attached gingival, should thus be included in the therapy plan when augmentation is planned in the molar area.

A cortico-cancellous block is usually preferred when the height of the posterior mandible is to be reconstructed. Adequate volume of this material is easily available from the iliac crest and, in contrast to most autogenous and allogenic alternatives, it offers stability to implants during the time it acts as a scaffold for new bone formation. The drawback with this material is that the degree of resorption is unpredictable. It is imperative to carve the transplant to an exact fit and to secure the transplant firmly to the recipient. As the residual amount of bone is unpredictable a two-stage procedure is preferred where the implants are inserted about 4 months after the transplantation.

In a few selected cases another approach may be chosen; if adequate stability can be obtained by inserting the implants one third to two thirds of their lengths into the mandible, compressed cancellous bone mixed with 20–30% allogenic bone substitute may be added around the implants to form a crest of adequate size for the implants. In this case the allogenic bone is used as a temporary filler, to increase the volume of the bone and, more importantly, to reduce the speed of resorption to allow adequate bone formation. The use of a contoured titanium mesh membrane to reduce the pressure on the graft is highly recommended in these cases. Alternatively,

the implants themselves may reduce external pressure on the graft by acting as “tent poles”.

Lateral onlay

There are three principle methods for widening a thin alveolar crest. Usually cortico-cancellous block grafts from the chin or lateral part of the corpus/ramus are used. Again, the graft should be contoured to a perfect fit to the recipient surface and secured by screws (Fig. 22.7a). If the cortical plate is thin, the vascularization offered by the recipient is usually less than when onlays are used to increase the vertical dimension. Hence, the risk for resorption may be higher and the “take” of the graft is usually slower and more unpredictable. The procedure is usually a two-stage procedure. When implants are placed 4–5 months after the transplantation there is still a risk of the graft loosening from the recipient crest.

In some cases vertical concavities with the diameter of the implants can be drilled into the buccal surface of the thin crest. The implants are then partly inserted into these concavities and secured apically in the cortex of the wider mandibular body. A particulate bone graft or particulate autogeneous bone mixed with hydroxyapatite could be packed between and buccal to the implants/crest and covered with a titanium membrane and left to heal for at least 6 months (Fig. 22.7b).

A third method is downfracture of the crest.³² After an incision 2–3 mm buccal to the top of the crest a vestibularly based buccal flap is raised and a horizontal cut is made along and almost through the crest, preferably with a thin fissure bur. The tip of the crest is then downfractured buccally to add to the width of

Fig. 22.7 (a) Schematic sketch of a buccal on-/inlay graft. A lateral box has been cut in the sloping buccal wall of the mandible and an onlay that has been adapted to fit this box tightly is secured to the recipient site. The implant seats are then drilled through the onlay/inlay into the mandible and the implants are placed. (b) Schematic sketch of a buccal onlay graft. Implant seats are drilled into the mandibular body and the implants placed. Due to the thin crest only the apices of the implants are secured into the mandibular body. An onlay graft is then cut/drilled to as good a fit to the mandible and implants as possible, gaps are filled with particulate bone, and the graft is secured to the recipient site. (c) Schematic sketch of a crestal downfracture.

base of the crest (Fig. 22.7c). The advantage of this method is that the blood supply to the “transplanted” bone is preserved by the soft tissue attachment. The drawbacks are that the height of the crest is reduced, the final width of the crest cannot be controlled, and attached gingiva is lost on top of the newly formed crest.

Distraction osteogenesis in the posterior mandible

Alveolar distraction was introduced by Chin and Toth in 1966.³³ This procedure has advantages compared to onlay grafting; the result is usually more predictable and there is no soft tissue displacement.^{34–37} The latter is especially important in the posterior parts of the mandible as the vestibule and the attached gingiva can be preserved. On the other hand distraction implies patient compliance during distraction and consolidation, more visits, and the added cost of the appliance. Control of the appliance and the vectors can be complicated,^{38–40} especially as the space for the appliance in the vestibule is limited in the posterior mandible. It follows that mechanical problems with the device as well as unplanned displacement and tipping of the transport segment are not uncommon.⁴¹ Distraction involves pressure on both the reference and transport segment. Fractures of the reference segment, the basal bone, have been reported.⁴² Pressure on the superior, transport, segment may induce not only suture dehiscence but progressive surface resorption with eventual collapse or fracture of this segment if it is not thick enough.^{38,40,43–46} This means that distraction is increasingly more difficult to perform as the distance between the alveolar crest and the canal is reduced. To prevent fractures a bone height above the canal of at least 5–6 mm is recommended.^{33,41,43} The procedure seems to be well tolerated by most patients⁴⁷ but a high incidence of complications including bleeding, transient nerve damage, unplanned displacement or fractures of bone segments, malfunctions or fractures of appliance may occur; incidences between 0 and 100% have been reported.^{42–45,48,49} This may indicate that thorough preoperative planning and gentle surgical technique is a prerequisite for success. Awareness of this

together with the relative complexity of the procedure may limit the usefulness of the procedure to rather few, carefully selected cases.

Surgical technique

A horizontal incision is made in the vestibule corresponding to the area of the alveolar crest to be distracted (Fig. 22.8). Care should be taken not to damage the branches of the mental nerve at the anterior end of the incision. Superiorly directed relief incisions are made at both ends. At the posterior end this may be replaced by an elongation of the horizontal incision. The flap is raised to expose the lateral part of the mandible. However, the top of the crest should be exposed as little as possible. While the index finger is placed against the lingual side of the mandible a horizontal osteotomy is made almost through the mandible not closer than 3 mm to the anticipated level of the neurovascular bundle. A medium-sized fissure bur is ideal for this purpose as it is readily felt by the index finger before the soft tissue is lacerated; a reciprocal saw is harder to control. Two vertical cuts are made through the crest at both ends of the horizontal cuts, slightly converging downwards. With the index finger still in place, the transport segment is then fractured from the rest of the mandible by means of a chisel. The distractor is then secured to the transport segment and the basal bone with mini-screws and activated to check that the transport segment may move freely and that the vectors are correct. Finally the distractor is inactivated and the flap resutured. After a latency period of 1 week the distractor may be activated for distraction by 0.5 up to 1.0 mm/day. An overcorrection of 1–2 mm is recommended. After a consolidation period of 4 months the implants are placed. The distractor should be in position until the implants are placed.

Penicillin V is administered: 2 g preoperatively and 2 × 2 g postoperatively until the suture lines are healed.

Nerve transposition

There is widespread confusion in the literature as to what this procedure should be called. The terms lat-

Fig. 22.8 Schematic sketch of the principles of distraction osteogenesis in the posterior mandible.

eralization, transposition, and repositioning are frequently used interchangeably. In this text, *nerve lateralization* includes procedures where the nerve is manipulated laterally posterior to the mental foramen. *Nerve transposition* is defined as a procedure where the neurovascular bundle is manipulated laterally after the incisor branch has been cut. This procedure was originally used to facilitate orthognathic surgery of the anterior mandible.⁵⁰ The area of the mental foramen is thus included. The expression *nerve repositioning* means "placed in the original position"; it is not applicable in this context and should be avoided.

The main advantage of nerve transposition and nerve lateralization is that both these methods permit installation of implants in cases where other methods would fail or be impossible to use. They may thus be regarded as "rescue operations". Both methods offer bicortical implant stability. The implant survival rate is high, around 93–95%.⁵¹ Marginal bone resorption does not differ from what is found after conventional implant placement^{51,52} and less than after distraction.⁴⁹ Once the surgeon is familiar with the procedure it is a quick procedure that can be made under local anesthesia. Nerve transposition may also be used to preserve neurosensory function in association with mandibular hemiectomy/reconstructions.

However, the procedure involves repeated trauma to the neurovascular bundle; the first trauma occurs when the incisor branch of the nerve is cut and a reactive swelling of the nerve follows. This swelling may induce a so-called compartment syndrome within the nerve trunk resulting in a "strangulation" of the vessels and hence lack of neurosensory function. The second trauma occurs as the nerve trunk is manipulated out of the mandibular canal.⁵¹ The alpha-fibers of the nerve are highly sensitive to traction. If the nerve is bent at any point up to approximately 5%, temporary neurosensory disturbances will occur. Normal sensation may be expected within 4–6 weeks although it may take considerably longer in some cases.^{51,53–55} However, if the traction is more than 5% the perineural vessels will rupture and permanent lack of neurosensory function or deficit function will result.^{53,56} Immediate postoperative loss of sensation or deficit nerve function can be expected in most cases but gradually normal neurosensory function is regained. Six to 12 months postoperatively only a few percent of the patients have persistent loss of sensation and some of these patients do not seem aware of this.^{51,56–58} In a study on 100 cases⁵¹ approximately 80% of the cases had no or deficient sensibility 1 week postoperatively, 25% 6 months postoperatively and 6% 18 months postoperatively. If corticosteroids are administered to reduce the peri- and postoperative swelling of the nerve, normal function seems to be regained a little earlier but the end result is approximately the same.⁵⁹ Although these figures may seem encouraging, patients seem to find it harder to accept nerve disturbances following nerve lateralization/

transposition than after, for example, sagittal split operations. It may be the implant patients are generally older and find it harder to adapt or there may be some quality factor in the nerve disturbance not registered by the method used. Some authors have advised against the use of this method as a routine procedure.^{60–63} Devitalization of the incisors after nerve transposition has not been reported, not even after bilateral procedures.

As the cancellous bone of the mandible is widely exposed during surgery and as the devitalized buccal cortex is reused in particulate form, the administration of antibiotics is imperative to avoid severe infections that have occasionally been reported.^{51,57} In extensively resorbed cases where the "buccal window" will cover most of the buccal surface there is a certain risk of mandibular fracture, especially if the seats are drilled deep into or through the cortex at the base of the mandible leaving only the lingual cortex to stabilize the mandible.^{64–66} The risk is most acute 1 week postoperatively when the decalcification phase of the remodeling coincides with the patient regaining full chewing force. However, it should be pointed out that fractures in conjunction with conventional implant placement in the posterior mandible have been reported.^{67–69}

Surgical technique

A subperiosteal flap is outlined by an incision along or slightly lingual to the top of the alveolar crest with a deep relieving incision into the vestibule anterior to the position of the mental foramen. To protect the anterior branches of the mental nerve, this should not be positioned too close to the mental foramen or made too vertical. Usually it is advantageous to add a posterior relieving incision. The flap is raised to expose the crest and buccal surface of the mandibular body, the mental foramen, and the base of the mandible. The subperiosteal dissection should continue into the mental canal to free the endosteum from the surrounding walls. A panoramic radiograph can usually provide information about the approximate level and course of the mandibular canal; the mental foramen indicates the highest point of the canal in the mandibular body. With a thin dissector between the roof and the nerve in the mental canal, a horizontal cut, parallel to the base of the mandible, is made from a point at least 6–8 mm anterior to the mental foramen and at the level of the roof of the mental canal, until a point some 8–10 mm posterior to the planned position of the most posterior implant seat. This horizontal cut should be made through the cortex and 1–2 mm into the cancellous bone. A second cut, as long as and parallel to the first, is made below the anticipated level of the mandibular canal. This cut involves two difficulties: access below the mental foramen and estimation of the level of the canal. To facilitate access to the area below the mental foramen a very shallow cut could be made through the periosteum/

endosteum that covers the nerve branches as they leave the foramen. This will expose the neurovascular bundle, usually the two main branches, and allow the flap to be retracted a little further. A correct estimation of the level of the floor of the canal is crucial. If the cut is not made into the cancellous bone but into the cortex of the mandibular base, the subsequent steps of the procedure will be more difficult and there is a definitive risk for mandibular fracture. If the cut is made too high, the nerve will be damaged. All cuts are made by means of a thin fissure bur. When in doubt the cut could be prepared by using a thin round bur to localize the correct position of the cut. Once the two horizontal cuts are made, these are united at both ends, in front of the foramen into the cancellous bone and at the posterior end only just through the cortex to avoid accidental cutting of the nerve (Fig. 22.9a). The thin elevator is again inserted into the mental canal and the roof of the canal is cut with a fissure bur, starting from a position adjacent to the elevator and working upwards in a V-form to remove the cortical roof of the mental canal. The buccal bone plate encircled by the cuts is then gently removed (Fig. 22.9b, c). The course of the mandibular neurovascular bundle in the mandible, the furcation at the mental foramen and the incisor branch are exposed (Fig. 22.9d, e). Usually small remnants of bone on top and below the bundle have to be removed with an elevator to free it completely. The incisor branch is cut some 7–8 mm anterior to the furcation and, starting from the mental foramen area, the neurovascular bundle is carefully lifted out of the mandible (Fig. 22.9f). It should be noted that the main trunk will start to retract and swell as a response to the trauma when the incisor branch is cut (Fig. 22.9f).

When the nerve is dissected out of the mandibular body care should be taken not to bend the nerve as this will induce neurosensory disturbances. Usually the nerve is more easily removed and the bleeding less, the longer the patient has been edentulous, as the small nerve fibers and vessels that earlier ran to the teeth are vestigial. While the nerve trunk is gently protected the implant seats are drilled, making only small impressions in the basal cortex, and the implants are inserted. They should be lightly stabilized against the cortex in the base of the mandible but not necessary perforating it, as this may increase the risk for mandibular fracture. It has been shown that the nerve trunk may be repositioned into the mandibular body protected from the implant surfaces by a resorbable membrane⁷⁰ or even without a membrane⁷¹ (Fig. 22.9g); however the author prefers to avoid direct contact between the implant and the nerve trunk in case an infection develops around an implant or the implant has to be removed for other reasons.

The bone plate that was removed earlier is cut into 2–3 mm pieces that are packed between and buccal to the implants while the neurovascular bundle is allowed to leave the mandibular body distal to the most posterior implant (Fig. 22.9h). Eventually a new

foramen will be formed in this area (Fig. 22.2). Cover screws are placed and the flap resutured. The patient is given penicillin V (2 g) and corticosteroids (4 mg) preoperatively. Later the same day the patient is given penicillin V tablets (2 g) and corticosteroids (3 × 4 mg). Penicillin V (2 g) is given for another 10 days postoperatively and corticosteroids are given, reducing the dose as follows: 4 × 3 mg the first, 4 × 2 mg the second and finally 4 × 1 mg the third postoperative day. Fig. 22.9i shows the postoperative radiographic result.

In cases of extreme resorption where the neurovascular bundle is close to or on top of the crest, the superior cortex is removed to reach the nerve which should be transpositioned posteriorly and into the lateral wall of the mandible. In these cases the crest should be allowed to heal before the implants are placed and the procedure should thus be performed as a two-stage procedure where the implants are inserted approximately 6 months after the transposition of the nerve.

Nerve lateralization

Nerve lateralization is one of the procedures indicated when implants are to be inserted posterior to the mental foramen (preferable from the first molar) and the height above the canal is inadequate. The method seems to offer both advantages and disadvantages compared to nerve transposition; as the area of the mental foramen is not involved, the procedure could be expected to be faster and easier to perform, and as the incisor branch of the nerve is not cut, one trauma less is inflicted on the nerve. On the other hand localized traction has to be applied to the nerve when the implants are placed and postoperatively it may come to rest against the threads of the implant which may constitute an additional long-term trauma. As the anterior cut through the cortex is placed in an area where the nerve runs close to or, in some cases, actually within the buccal cortex when nerve lateralization is performed, there is an increased risk of accidentally cutting the nerve in this area.

Due to better access, implant placement in the area of the second premolar seems to be facilitated by nerve transposition. Otherwise the results of the two methods seem comparable; neither implant survival nor postoperative neurosensory function seem to differ significantly.^{72,73} Hence, the choice of method seems to be up to the personal preferences of the surgeon.

Surgical technique

The flap design is identical to that used in nerve transposition. It is important to expose the mental foramen to help localize the level of the canal but the dissection is not continued into the mental canal. In the area where implant placement is planned two

Fig. 22.9 (a) Schematic sketch of nerve transposition. The outline of the cortical window, later to be removed. The window includes the mental foramen. The superior, inferior, and anterior bone cuts are well into the cancellous bone; the posterior, however, is only almost through the cortex to avoid trauma to the neurovascular bundle. (b) The roof of the mental canal has been removed. The buccal window is gently being removed. (c) Clinical illustration of (b). (d) The buccal cortex has been removed. Schematic sketch. (e) Clinical view of (d). At the furcation the rather thick main trunk divides into a thinner mental branch and an even thinner incisor branch. Note that the nerve is situated more lingually in the posterior part of the mandible. (f) The incisor branch is transected and immediately starts to contract and swell as it is gently removed from the mandibular body. (g) The implants are placed. (h) The former buccal cortical window is cut into bone chips that are placed between and lateral to the implants. The neurovascular bundle now leaves the mandibular body posterior to the implants where eventually a "retromolar foramen" will be formed. (i) Radiographic view after implant placement.

horizontal cuts are drilled 1–2 mm into the cancellous bone, parallel to the base of the mandible, by means of a thin fissure bur, one about 2 mm superior to the anticipated level of the neurovascular bundle and the other below the mandibular canal. As in nerve transposition the level of the lower cut is the hardest to place correctly and any misjudgement involves the same risks. The horizontal cuts are then united by vertical cuts at both ends, at the posterior end only just through the cortex to avoid accidental cutting of the nerve (Fig. 22.10a). The anterior cut has to be made through the cortex which involves a certain risk of cutting the nerve if this is close to or within

the cortex. A more cautious cut that does not penetrate the cortex will make luxation of the buccal cortex and dissection of the nerve much more difficult, riskier and time consuming. To prevent accidental cutting of the nerve, preoperative tomograms are recommended.

When the buccal bone plate has been removed any small remnants of bone on top and below the nerve bundle are removed with an elevator to facilitate lateralization of the bundle. This has to be done more carefully than when transposition is performed as the medial part of the nerve bundle has to be accessible from a lateral approach. The neurovascular bundle is

then gently pulled 2–3 mm (or as required) out of the operation field. The author uses a home-modified instrument; a small dissector with the tip bent 120°. As has been pointed out above it is extremely important to apply only gentle traction to the nerve to reduce the risk of nerve damage. As in nerve transposition the nerve may start to swell as the vessels within the trunk rupture, but the swelling is usually less than when transposition is performed. The implant seats are drilled only a couple of millimeters into the basal cortex. The implants are placed and the neurovascular bundle is allowed to slip back into the mandible (Fig. 22.10b). Frequently the bundle contracts to lie against the treads of the implants. The long-term neurosensory impact of this is not known. To avoid a postoperative buccal concavity in the mandible the bone plate that was removed earlier can be cut into 2–3 mm pieces that are gently packed between and buccal to the implants and the neurovascular bundle. Any pressure should be avoided. Cover screws are placed and the flap resutured. The patient is given penicillin V 2 g preoperatively and 2×2 g postoperatively for ten days as well as corticosteroids 4 mg preoperatively and 3×4 mg postoperatively on the day of operation and 4×3 mg, 4×2 mg and 4×1 mg, respectively the following postoperative days.

Nerve repair

In principle, three types of damage may be inflicted on the mandibular nerve during implant surgery: superficial damage to the nerve sheath without damage to the nerve fascicles, damage to both the sheath and various numbers of fascicles, and complete interruption (transection) of the nerve bundle.

A solitary superficial injury to the nerve sheath is most likely to occur during drilling of an implant seat and during drilling the bone cuts for nerve distraction osteogenesis, transposition, and lateralization. This type of damage does not call for repair as normal function is usually re-established.⁷⁴

A combined injury to the nerve sheath and nerve fibers can be inflicted by deeper cuts during the procedures mentioned above, by pressure induced by inserting an implant too deep or by compartment syndrome brought about by swelling of the nerve due to external trauma, such as cutting of the incisor branch or rupture of multiple small dental vessels/nerve fibers. These injuries usually result in nerve entrapment by scar tissue that can itself worsen the neurosensory dysfunction and may make it permanent. It is thus important to establish the nature of the damage as soon as possible.

If the damage is caused by direct pressure from an implant inserted into the canal the implant should be rotated counter-clockwise until its tip is level with the roof of the canal. If the damage is caused by compression of the roof of the canal by an implant inserted further than has been drilled, the implant should also be rotated counter-clockwise to relieve the pressure on the nerve. However, sometimes an open procedure is needed to reduce the pressure on the nerve. Access to the area is described under the procedure for "nerve lateralization". In both cases action should preferably be taken within a week. Usually normal sensation will be regained within another week or two.

If some or all fascicles have been damaged due to swelling, the patient usually loses sensation in the lip/chin but normal sensation is usually regained in the region corresponding to the primarily undamaged fascicles. In a best-case scenario, depending on how much laceration of the fascicles has been caused by the trauma, sensation may return even in the areas served by the damaged fascicles. This usually happens within 3–6 months, up to a year. In some cases, however, an internal or external scar is formed. If such a scar has formed, sensation in the damaged fascicles will not return spontaneously. If an external scar is formed the nerve is gradually strangulated and sensation will be permanently lost in the whole sensory area of the nerve. In these cases, lysis should be performed to save the neurosensory function. Satisfactory results have been reported after external

Fig. 22.10 (a) Schematic sketch of nerve lateralization. Outline of the buccal window. The mental foramen is not included in the window. (b) The cortical window has been removed, and the nerve trunk is gently pulled buccally as the implants are placed.

neurolysis as late as 12–24 months after the trauma.^{75,76} The procedure is best performed using 10× magnification. The damaged part of the nerve is exposed as described above, the bundle is gently pulled out of the canal and the scar tissue, which is usually easily identified, is excised by means of a pair of microscissors or a scalpel. Even internal scar tissue can be excised or the damaged part may be resected. Excision of an internal scar is a delicate task and is best left to an experienced microsurgeon. The author prefers to resect the damaged part, adapt the ends and suture the nerve.

The mandibular nerve bundle is elastic to a certain degree. Therefore, when the nerve is transected the nerve ends contract and a gap is formed between the ends. Only in exceptional cases will normal function be regained. The nerve should be repaired as soon as possible. The traumatized area is exposed as described above. If the cut is not clean the nerve ends should be trimmed into undamaged tissue and the ends are adapted. This, however, is usually not possible without tension due to the elasticity of the trunk and the necessary resection. An autogenous vein graft⁷⁷ or Gore-Tex tubing (Gore Company, Flagstaff, AZ, USA)^{78–81} may be sutured to the epineurium of the proximal and distal nerve trunks and used as a conduit for regenerative repair. However, this assumes that the gap is only a few millimeters wide,^{77,78} otherwise a nerve graft should be interposed. Again, this requires a specialist in microsurgery. The author prefers to perform a nerve transposition with transection of the incisor branch after which the ends can be adapted without tension. Ideally, each fascicle should be sutured to its counterpart. However, good clinical results may be obtained by removing the epineurium 3–4 mm from both cut ends, carefully aligning the ends without major consideration of adapting the individual fascicles and suturing the ends in this position. The sutures, as few as possible, are placed superficially in the perineurium.

One difficulty can be understood from the discussion above. In quite a few cases normal sensation will return after moderate damage to the mandibular nerve. Thus, as nerve repair is not a familiar procedure to most surgeons and not always successful there is a good case for a “wait and see” strategy. On the other hand delay involves an increased risk for permanent damage^{82–85} as nerve cells in the trigeminal ganglion are successively lost after transection of the nerve. It seems that nerve repair prevents further loss of nerve cells in the ganglion but those already lost at the time of repair are not re-established.⁸⁶ Unfortunately, the sparse clinical literature offers very limited evidenced-based knowledge on methods and timing of mandibular nerve repair.^{87,88} However, a useful rule of thumb may be that transections and deep cuts of the nerve should be repaired immediately by tension-free primary suturing, while it may be defensible to postpone nerve repair up to 6 months after superficial damage.^{75,76}

Ethical considerations

Before every single operation the surgeon should consider the balance between what the patient may gain and the risks involved. Implant surgery is an elective procedure; it does not save lives or prevent disablement. Hence, the surgical risk should be moderate. Unfortunately, it is not possible to give general recommendations on what level of risk is justifiable; that depends on each case and each patient. Some of the procedures discussed above are well proven and should be safe, others involve moderate risks and discomfort, while still others involve considerable risks for failure, pain, impairment, and may even prove fatal.

Although some of these procedures require considerable practice and skills, the real challenge for the surgeon is to judge each case from its own surgical as well as psychological merits to be able to offer the patient individual advice. The author has a conservative rule of thumb: “Would I recommend this procedure to someone in my family?” If the answer is no, why recommend it to a patient?

Chapter 23

Autogenous Bone Harvesting Techniques

George K.B. Sándor, David K. Lam, Leena P. Ylikontiola, Vesa T. Kainulainen, Kyösti S. Oikarinen, and Cameron M.L. Clokie

This chapter is an overview of different techniques for harvesting autogenous bone graft. The needs for bone graft based upon anticipated volumetric and structural needs are discussed. The chapter describes intraoral harvesting sites, including mandibular symphysis, ramus and retromolar area, maxillary tuberosity, coronoid process, mandibular and maxillary tori, and zygomatic body. Extraoral harvesting sites include anterior and posterior iliac crest, costochondral area, tibial, fibular and ulnar bone graft. The surgical techniques in the different anatomic sites are described in detail and the potential risks for complications are also included in the chapter. The authors conclude that reconstruction of osseous defects in the maxillofacial region is one of the most challenging tasks to the reconstructive surgeon.

lenging tasks to the reconstructive surgeon. The goals of bony reconstruction of the craniomaxillofacial skeleton are to restore:

1. Morphology and position of the reconstructed bone in relation to its opposing jaw and the other facial bones.
2. Adequate bone height and width.
3. Continuity of the maxilla, mandible, and the other facial bones.
4. Facial contour and support for overlying soft tissue.

Bony reconstruction of the craniomaxillofacial complex can be accomplished by a variety of materials and techniques. While many bone substitutes¹ are available (Fig. 23.1), autogenous bone grafts remain the “gold standard” for reconstruction.^{2,3} Autogenous bone has been demonstrated to be superior to allogeneic bone, xenogeneic bone, bone substitutes, and alloplasts in terms of the form, function, and adaptability.⁴ Moreover, autogenous bone is osteoinductive, osteoconductive, and immunologically safe.⁵

Fig. 23.1 Coral granules being placed into mandibular alveolar ridge after the removal of an ankylosed mandibular second deciduous molar in a growing pediatric patient. Such bone graft substitutes may be useful in alveolar ridge sparing or reconstruction procedures; however, the current gold standard for bony reconstruction in the craniomaxillofacial skeleton is autogenous bone.

Introduction

The need for bone

Reconstruction of osseous defects in the oral and maxillofacial region represents one of the most chal-

Recent developments in bone graft harvesting techniques have reduced patient morbidity and improved treatment outcomes.^{6,7} The majority of bone grafts in the maxillomandibular region are performed to reconstruct alveolar bone in order to provide complete functional rehabilitation with osseointegrated dental implants. Other indications for bone grafting may include, but are not limited to, orthognathic surgery, craniomaxillofacial surgery, restoration of traumatic defects, reconstruction of ablative defects left by tumor surgery, and temporomandibular joint reconstruction.

Several donor sites are available to the surgeon for autogenous bone harvesting.^{8,9} The most commonly used intraoral sites (Fig. 23.2) include the maxillary tuberosity and mandibular symphysis, ramus, and retromolar areas, while the most common extraoral sites are the ilium, costochondral area, calvarium, and tibia. Intraoral bone harvesting can usually be performed under local anesthesia alone or local anesthesia combined with nitrous oxide–oxygen sedation, intravenous sedation or oral premedication, as necessary. In contrast, extraoral harvest sites usually require general anesthesia and hospitalization of the patient. A thorough knowledge of the characteristics and limitations of intraoral and extraoral bone harvest sites is important for surgeons, but also for general dentists and other specialists, in order to provide accurate information to their patients and appropriately refer them for reconstructive surgery. The purpose of this chapter is to discuss the indications and techniques for autogenous bone harvest sites for oral and maxillofacial reconstruction as well as to point out the advantages and disadvantages of these various sites.

Choosing a harvest site based upon anticipated volumetric and structural needs

Human bones can be categorized as endochondral and intramembranous bones. Facial and calvarial

bones are of intramembranous origin while almost all other bones used for bone graft harvest (ilium, costochondral tissue, and tibia) are of endochondral embryonic origin. During intramembranous ossification, mesenchymal cells differentiate into osteoid-producing osteoblasts. Endochondral bone originates from a cartilage matrix which slowly calcifies to bone. There is both experimental and clinical evidence which suggests that intramembranous bone grafts undergo less rapid resorption than grafts of endochondral origin (ilium, costochondral tissue, and tibia).¹⁰ It has been proposed that intramembranous bone grafts revascularize more rapidly, which enhances early healing and allows for a more predictable maintenance of volume, than endochondral bone grafts.^{11–13} This phenomenon may be explained by the similar embryonic origin of both the donor and recipient site bone in the oral and maxillofacial region. However, at present, there is little definitive evidence in humans to demonstrate that this difference truly exists.

Bony reconstruction begins with assessing the bone to be reconstructed.³ The defect location, size, and relationship to adjacent structures are the main factors to consider in planning an esthetic and functional reconstruction.^{6,7,14} Thus the surgeon should first determine the quality and quantity of bone needed for reconstruction of the maxillofacial defect in order to choose the most appropriate donor site (Fig. 23.3). Clinical examination, and panoramic, occlusal, and periapical radiographs yield the basic information which will allow for the evaluation of bone volume and for the identification of any pathological lesion in the area. Additional imaging such as panoramic tomograms or computed tomography may also be used.

If a particulated graft is chosen then the surgeon must remember that the graft will serve as a nidus for osteogenesis but it will not have any structural integrity. If a cortical graft is chosen then it will have a slower resorption and integration into the recipient bed.

Fig. 23.2 Anterior and lateral views of skull diagrams showing the possible sites for autogenous intraoral bone graft harvesting. Site A: menton or chin mandibular harvesting site; Site B: mandibular ramus harvesting site; Site C: maxillary tuberosity harvesting site; Site D: mandibular coronoid process harvesting site; Site E: zygomatic harvesting site.

Fig. 23.3 (a) Defect in anterior maxilla left by the removal of a large odontogenic keratocyst. Note labial deficiency of bone with dehiscence revealing the exposed labial threads of the implant fixture placed at the left maxillary canine site. (b) A template is fashioned from bone wax to give the surgeon the dimensions of the required bone graft to satisfy the requirements of the area to be reconstructed. (c) Cross-sectional view of the bone wax template of the deficient alveolar ridge. (d) Autogenous bone graft material harvested from the flutes of the spiral drill used to prepare the implant sites. (e) Autogenous bone graft material harvested solely from the implant preparation sites using both the flutes of the spiral implant site preparation drills and a specially designed suction trap. (f) The particulate autogenous bone graft deposited over the dehiscence of bone in the area of the maxillary left canine to cover the exposed implant threads and to replace the deficient bone.

Cortical or cancellous graft?

Bone harvested from intraoral donor sites is mainly cortical in nature. In the symphyseal area, variable amounts of cancellous bone can also be harvested, but the volume may be limited.¹⁵ Cortical bone blocks from this region can be rigidly fixed in place using osteosynthesis screws or can be easily particulated with a bone mill. Rigidly fixed onlay grafts avoid the potential migration which can occur with particulated grafts. One problem with onlay block grafts is that they are prone to mucosal dehiscence if tension-free soft tissue closure is not achieved. In most cases, loss of the graft is due to wound dehiscence or infection during healing.¹⁶ Stable fixation of the graft along with small perforations of the cortical bone at the recipient site appear to improve graft union. This is most likely the result of an increase in the availability of osteogenic cells and the improved revascularization of the graft.^{17,18}

Particulated mandibular cortical bone grafts can be used as a paste in sinus lifts,¹⁹ in filling alveolar defects, in onlay grafting,²⁰ and in alveolar clefts.²¹ Particulated grafts from the symphysis to the maxillary sinus seem to maintain their volume well and are able to form new bone in 6 months.¹⁹ Bone chips collected during implant bed preparation or bone graft harvesting with a bone suction trap can be used, for example, to cover exposed implant threads or as an additional grafting material with another intraoral donor site.²²

Due to resorption of an onlay block graft, a slight overcorrection or overgrafting of the defect is generally recommended. Cancellous bone grafts resorb faster than cortical grafts. Therefore more overgrafting is needed if mainly cancellous bone is used. Cancellous bone grafts are remodeled faster than cortical grafts and this is probably due to the greater numbers of living cells found in cancellous bone. Also, revascularization is faster as blood vessels have difficulties in penetrating cortical grafts. The suggested healing time for bone grafts is usually 4–6 months, as extended healing periods without functional loading may enhance more bone resorption.^{23,24} An algorithm for graft harvesting is presented in Fig. 23.4.

Intraoral harvesting sites

The most significant advantages of the intraoral harvesting sites (Fig. 23.2) are that the harvesting can be done under local anesthesia as an outpatient procedure, the local donor sites have convenient surgical access, and the ischemic time of the bone graft is short. In addition, since both the donor and recipient sites are intraoral, there is no morbidity from a second surgical site such as a visible extraoral scar.^{10,21} However, the major disadvantage of intraoral harvesting is the limited amount of bone available and, as such, the small quantity may be insufficient for moderate to large defects.⁸ In addition, the harvested

Fig. 23.4 An algorithm to help determine the most appropriate harvesting site for the reconstruction of a particular defect of bone in the craniomaxillofacial skeleton. First the quantity of bone required is considered. Then the quality of bone needed is determined, usually by structural requirements or the resistance to resorption. Finally a site is chosen which is determined by the quantitative and qualitative requirements of the defect to be reconstructed. This is balanced with the concept of the minimization of donor site morbidity, which is always kept in mind. (AICBG = anterior iliac crest bone graft; PICBG = posterior iliac crest bone graft.)

bone is almost completely cortical. Possible complications of intraoral harvesting include endodontic problems, neurosensory disturbances, infections, and wound dehiscence.²⁴ The various intraoral donor sites are discussed below.

Mandibular symphysis

Bone quality and quantity

Mandibular symphyseal bone has been used successfully in secondary alveolar cleft bone grafting,^{10,21} maxillary sinus grafting,¹⁹ grafting alveolar defects

before placement of dental implants,^{16,20} reconstruction of the orbital floor,²⁵ and with Le Fort I osteotomy.²⁶ The anterior mandible is the intraoral donor site producing the largest amount of bone (Fig. 23.5). The average volume of bone harvest available from the symphysis is in the range of 1.7–4.7 ml and the maximum average block size is approximately 21 × 10 × 7 mm.^{15,24} This amount of bone would facilitate a 7 mm increase in ridge width over a 21 mm mesio-distal distance. Particulating the symphysis graft with rongeurs or a bone mill will usually allow for a unilateral sinus lift procedure. Some cancellous bone can also be harvested from the symphysis but the

Fig. 23.5 (a) Horizontal osteotomy of anterior cortical layer in a chin graft harvesting procedure. (b) Once the superior, inferior, and lateral osteotomies of the anterior surface of the anterior mandible are completed an osteotome is used to remove the anterior cortex of the mandible. (c) The anterior cortical plate of the chin is being removed. (d) Two harvested cortical plates. The specimen on the left illustrates the nature of the inner aspect of the graft which contains cancellous bone. (e) More cancellous bone can be harvested from the deeper parts of the bony wound once the outer cortical plate of the mandible is removed. (f) A cadaveric specimen showing an alternative method of bone graft harvesting from the chin. A trephine can be used to harvest circular pieces of cortical bone. Once the circular pieces of cortical bone are removed this technique also gives access to the cancellous bone found deep to the outer cortical plate of the mandible. The volume of available cancellous bone in this area can be quite variable and unpredictable.

quantity is highly variable and at times only small amounts can be collected. If cancellous bone is preferred for a reconstruction, an alternative donor site should be considered.¹⁵

Technique

The operation can be performed under local anesthesia. Bilateral inferior alveolar and mental nerve blocks are given. Infiltration with vasoconstrictor-containing local anesthetic in the symphyseal soft tissue reduces bleeding during the operation.

After allowing adequate time for vasoconstrictor effects to take place, the incision is initiated in a layered approach through the labial mucosa and is continued through the mentalis muscles and periosteum. Exposure of the symphyseal bone is undertaken using periosteal elevators and the mental nerves are visualized bilaterally. The roots of the incisors and canines should be localized and bone cuts should be made at least 5 mm inferior to the root apices. The roots of canines can impede the operation and limit the size of graft. Similarly, the surgeon should stay at least 5 mm away from the inferior border of the symphysis and the mental foramina. Bone cuts can be made with a bur or reciprocating saw under copious saline irrigation. When the desired bone cuts have been completed, thin straight or curved osteotomes are then used to deliver the graft. The midline symphysis is usually left intact, and monocortical grafts can be harvested from the right and left sides simultaneously as necessary. It is possible to harvest a bicortical bone block

with this technique but it is not recommended because this may cause postoperative complications including significant pain, swelling, bleeding, endodontic problems, fracture of the mandible, sleep apnea, and loss of chin contour. As such, it is preferable to harvest a monocortical block and use curettes to scoop any necessary cancellous bone. Alternatively a trephine can be used to obtain the graft.

Hemostasis can be achieved using resorbable hemostatic agents or fibrin glue. Long-lasting local anesthetic, e.g. bupivacaine, can be applied to the area to achieve longer analgesia. The wound closure is done in two layers with a resorbable suture for the muscle layer and fast-resorbing suture for the mucosa. Flexible skin tape can be used on the chin for 3–5 days to reduce swelling and prevent wound dehiscence. Temporary chin paresthesia has been documented in at least 43% of patients.²⁷

Mandibular ramus and retromolar area

Bone quality and quantity

The lateral side of the mandibular ramus and retromolar areas are sources of mainly cortical bone suitable for onlay grafting.²⁸ The mandibular retromolar area is a relatively easy site for cortical bone harvesting (Fig. 23.6). Bone can be harvested from the buccal side of the mandible in the second and third molar area and distal to the molars.^{24,28,29} Mandibular ramus and retromolar areas are associated with fewer com-

plications than the symphyseal site.²⁴ The bone block from this area can be as large as 35 mm in length, 10 mm in height, and 4 mm in thickness and the average volume is 0.9 ml,²⁴ but the average size is usually about 16 mm in length, 9 mm in height, and 4.5 mm in thickness, and the volume varies between 0.5 and 1.5 ml.⁸ The block size depends upon the individual anatomy of the mandible and if larger blocks are harvested, the complications increase in incidence and severity.

Technique

The operation can be performed under local anesthesia. Inferior alveolar and buccal nerve blocks are given. After allowing adequate time for vasoconstrictor effects to take place, the incision can be placed in the gingival margin or in the buccal vestibule. A full-thickness mucoperiosteal flap is developed along the lateral aspect of the mandible, exposing the retromolar area and anterior lateral ramus. The size of the bone block needed is first measured and marked on the bone with a bur or a marking pen. The inferior alveolar nerve is near the buccal cortex,³⁰ and sawing or drilling should be performed with caution so as not to damage the neurovascular bundle. The osteotomy can be started anterior to the coronoid process at a point where adequate bone thickness is available. The osteotomy then continues along the anterior border of the ramus medial to the external oblique ridge. The anterior cut is placed in the mandibular body, in the molar region. The posterior vertical cut is made in the lateral aspect of ramus perpendicular to the external oblique osteotomy. The inferior osteotomy connecting the posterior and anterior vertical cuts is made with a bur in a straight handpiece (shallow cut to create a line of fracture). The bone block is released using a thin curved or spatula osteotome. Curettes

are used for cancellous bone harvesting. Sharp bony edges are smoothed with burs or bone files. Trephine burs for implant explantation can also be used to harvest bone cores. The retromolar area is also suitable for harvesting bone chips with a specially designed suction trap (CSMT, Mississauga, Ontario, Canada).^{8,22}

Bleeding is controlled and the wound is closed with a running resorbable suture for a sulcus incision or with interdental interrupted sutures if there was a gingival sulcular incision. Although rare, morbidity from this procedure may include mandible fracture, lingual or inferior alveolar nerve sensory disturbances, bleeding, and wound dehiscence.³¹

Maxillary tuberosity

Bone quality and quantity

Bone harvested from the maxillary tuberosity can be used to fill local alveolar defects before dental implantation.³² The volume of bone in the posterior maxilla is rather limited and the bone is mostly cancellous. It is possible to harvest small amounts of bone from the edentulous maxillary tuberosity, but if the second or third molars exist, this procedure is difficult (Fig. 23.7). This procedure is useful if additional bone is required to "extend" bone volumes in conjunction with other intraoral grafts. For example this may occur with maxillary sinus floor augmentation where it is quite simple to extend the incision and harvest more bone from the tuberosity area with drilling and a bone trap or by rongeurs.

Technique

The operation can be performed under local anesthesia. Local anesthetic with vasoconstrictor is infiltrated

Fig. 23.6 (a) Lateral cortical graft from the ramus of the mandible is being harvested showing the completed anterior, posterior, and medial osteotomies of the ascending ramus. (b) The cortical strut of bone harvested from the anterior ramus of the mandible. (c) The defect in the left ramus of the mandible left by harvesting of the ramal bone graft.

Fig. 23.7 Cadavaric specimen showing a lateral view of the maxillary tuberosity.

to the buccal and palatal sides of the maxillary tuberosity. After allowing adequate time for vasoconstrictor effects to take place, a midcrestal incision is made and the posterior maxilla is exposed. The borders of the maxillary sinus should be localized and bone can be harvested posterior to the sinus with rongeurs, burs or chisels. During harvesting, special attention should be paid not to perforate the maxillary sinus. Bleeding is controlled and the wound closed with resorbable sutures.

Coronoid process

Bone quality and quantity

Bone from the coronoid process has been used for orbital floor reconstruction after a blow out fracture,³³ for nasal augmentation,³⁴ and for paranasal augmentation in conjunction with orthognathic surgery.³⁵ A maximum of 20.9×21.8 mm of coronoid bone is obtainable but it is very thin with a thickness ranging from 4.6–7 mm,³⁵ contains only cortical bone and is not optimal for grafting in implant surgery (Fig. 23.2).

Technique

The operation can be performed under local anesthesia but removal of the coronoid process can be a difficult operation and usually requires general anesthesia. Local infiltration and inferior alveolar and buccal nerve blocks are given. After allowing adequate time for vasoconstrictor effects to take place, an intraoral incision is made in the buccal vestibule. A full-thickness mucoperiosteal flap is developed along the lateral aspect of the mandible, exposing the retromolar area, anterior lateral ramus, and anterior margin of the coronoid process. Total stripping of the attachment of the temporal muscle can be performed with a periosteal elevator or electrocautery. After exposing the entire coronoid process, it may be osteotomized using a fissure bur or reciprocating saw from the sigmoid notch to the anterior ramus. It is then removed

with the use of a Kelly or Kocher clamp. Sharp bony edges are smoothed with burs or bone files. Bleeding is controlled and the wound is closed with a running resorbable suture for a sulcus incision.

Mandibular and maxillary tori

Bone quality and quantity

Mandibular and palatal tori can be used, if present, for alveolar augmentation with mainly cortical bone.

Technique

Considerable amounts of bone can be harvested from tori with a suction trap. If a torus is removed as one block, it can be particulated with a bone mill (Cytagenix, Montréal, Québec, Canada) (Fig. 23.8) or used as a block graft. Small amounts of bone are sometimes needed, for example to cover exposed implant threads. In this case it is possible to harvest bone from nearby edentulous areas with burs and a suction trap.

Zygomatic bone

Bone quality and quantity

Zygomatic bone can also be used as a donor site for alveolar bone reconstruction.^{36–39} It is possible to

Fig. 23.8 (a) Bone mill in its fully assembled state used for mincing cortical grafts into a more particulated workable form. (b) The inner aspect of the bone mill.

harvest about 0.5–1.5 ml of bone from the zygomatic area. The complications and morbidity with this technique have been very mild and the procedure can easily be done under local anesthesia. A bone graft from the zygomatic eminence and arch area has also been used to graft the maxillary step osteotomy and interdental osteotomy gaps during segmental Le Fort I osteotomies.⁴⁰

Technique

The operation can be performed under local anesthesia. Local anesthetic with vasoconstrictor is infiltrated to the buccal vestibule. After allowing adequate time for vasoconstrictor effects to take place, zygomatic bone is exposed through a vestibular incision and bone can be harvested by a trephine bur or round burs and a suction trap (CSMT, Mississauga, Canada) (Fig. 23.9).²² Bleeding is controlled and the wound is closed in layers with resorbable sutures.

Extraoral harvesting sites

Extraoral harvesting sites are recommended when the need for bone graft material is greater than the volume of bone that the intraoral harvesting sites can safely provide.⁹

Ilium

The ilium is the preferred donor site for bone grafting to the maxilla and mandible. It contains the greatest absolute cancellous bone volume and has the highest cancellous-to-cortical bone ratio. These grafts may be harvested from either the anterior or posterior areas of the ilium (Fig. 23.10). Donor site complications may include seroma, hematoma, nerve and vessel injuries, gait disturbances, iliac fractures, peritoneal perforation, infection, sacroiliac instability, and pain. Paresthesia or anesthesia of the skin following iliac crest bone graft harvesting has been reported in 8–38% of patients.^{41–46} Use of drains at the anterior or

(c) Cadaveric specimen showing defect left by harvesting the zygomatic site with a large round bur to produce a particulated bone graft. (d) Clinical exposure of the zygomatic harvesting site using an intraoral incision in a living patient. (e) Harvesting site after preparation with a large round bur. (f) Particulate bone graft harvested from the zygomatic site collected by a specially designed bone trap. (g) Bone graft being gathered in preparation for transfer to the intraoral recipient site. (h) Zygomatic site seen just lateral and superior to implant placement site where bone graft material is needed. The zygomatic sites can be harvested by using spiral implant preparation burs and bone graft then removed by a suction trap. Note the proximity of the graft harvest site to the reconstructive site or recipient bed. Harvesting from nearby intraoral sites can help to reduce morbidity at the bone graft harvest site.

posterior donor sites are not mandatory and there is no difference in wound healing.⁴⁷

Anterior iliac crest – open

Bone quality and quantity

The anterior iliac crest has been used by oral and maxillofacial surgeons as a donor site for bone harvesting for decades.⁴¹ It is a dependable and versatile site (Fig. 23.11) allowing the harvesting of a predictable amount of cortical and cancellous bone for moderate-sized defects.⁴⁸ In some small individuals, however, the volume of bone harvested can be disappointing. In general, the anterior iliac crest should allow harvesting of 30–50 ml of bone.⁴⁹ The patients usually require postoperative hospitalization. The main limitation for the volume is that harvesting from medial and lateral plates should be avoided. If this is

done, the patient will have a high rate of morbidity after the operation. The risks and morbidity associated with this site include short- and long-term gait disturbances and lateral femoral cutaneous nerve paresthesia that can be quite troublesome to patients.^{41,50}

Technique

Anterior iliac crest bone graft harvest begins with site selection. Bone graft harvesting from the ipsilateral or contralateral side from the recipient site is mainly determined by the patient position relative to the anesthetic set-up and operating room team. After the nasoendotracheal tube has been passed to secure the patient's airway, the patient is prepared and draped in the customary manner for a two-team approach to this procedure. A separate field is used to avoid cross-contamination of donor and recipient sites, and as such the contralateral side is usually preferred.

Fig. 23.10 (a) Radiographic view of an anterior iliac crest harvest site. (b) Superior view of the bony skeleton of the anterior iliac crest.

Fig. 23.11 (a) Outline of the skin surface anatomy over the anterior iliac crest. The backwards facing “C” represents the location of the anterior superior iliac spine, or the origin of the sartorius muscle. The harvesting technique should avoid this landmark as the force of the pull of the sartorius muscle could fracture away its insertion if the harvesting is too close. Harvesting too close to the anterior superior iliac spine may also result in bothersome paresthesia in the distribution of the lateral femoral cutaneous nerve on the anterior thigh. This is a complication that may be avoided by harvesting more superiorly. (b) The anterior aspect of the iliac crest is exposed. Osteotomies have been performed superiorly and inferiorly staying at least 1 cm above at the anterior superior iliac spine. The medial aspect of the iliac crest is preferred by the authors. (c) The harvested corticocancellous block of bone from the anterior iliac crest. (d) The defect left by harvesting the inner aspect of the iliac crest.

The planned incision is first marked on the left or right anterior iliac crest following the appropriate anatomic landmarks: the anterosuperior iliac spine and anterosuperior iliac tubercle are marked along with the anterior iliac crest. The nerve branches that are most at risk are the lateral cutaneous branch of the subcostal nerve (T12) and the lateral cutaneous branch of the iliohypogastric nerve (L1). The lateral femoral cutaneous nerve is located anterior and medial to the anterosuperior iliac tubercle; careful delineation of landmarks will minimize damage to this nerve. The skin overlying the iliac crest is gently pulled superiorly and medially to allow the incision to rest in a position inferior and lateral to the iliac crest. The resultant scar should be in a position where it is not rubbed or chafed afterwards by a belt or clothing.

The incision is made parallel to the crest of the iliac bone and a 3–4 cm incision is usually adequate to gain access to the iliac bone. A long-acting local anesthetic with vasoconstrictor is infiltrated subcutaneously as well as subperiosteally. After allowing sufficient time for vasoconstriction, and local anesthesia to take effect, an incision is made through skin and subcutaneous tissue with a scalpel. Dissection can then proceed with electrocautery through the fat and down through Camper's and Scarpa's fascia, and on to the periosteum.

Once through the periosteum, the subperiosteal dissection can proceed on to the medial or lateral surfaces of the ilium, depending on the approach used and the need for a mono- or bicortical graft. In the anteromedial approach the subperiosteal dissection continues on to the medial side of the bone, being careful to preserve the tensor fascia lata attachment to

the lateral ilium in order to minimize gait disturbances and pain. A medially placed retractor may be helpful to protect the iliacus muscle and peritoneal contents. In the anterolateral approach, the periosteum is reflected from the lateral ilium for easier access but at a cost of increased incidence of gait disturbance. Following identification of this region, the required size of the graft is outlined, and using saws, osteotomes, or a bur, osteotomies are performed under copious normal saline irrigation. After the block is freed, further underlying cancellous bone may be harvested using a series of bone gouges and curettes. Once sufficient quantity and quality of bone are harvested, all sharp bony edges are trimmed with a bone rasp. Bleeding points are then attended to, and the wound is irrigated with copious amounts of normal saline. The wound is closed in layers: periosteum, fascia, dermis, and skin. During the graft harvest, the recipient site can be prepared simultaneously to save time if two teams are available.

Anterior iliac crest – trephine

Bone quality and quantity

The era of minimally invasive surgery has led to the development of new technologies and surgical approaches that minimize postoperative morbidities. Cores of cancellous bone, with diameters of 4.0 mm and lengths up to 30 mm, can be removed from the iliac crest with a motorized trephine (Fig. 23.12). It has been reported that as many as seven cores can be removed giving 4 ml of bone, which is suitable for moderate-sized defects.⁵¹

Fig. 23.12 (a) The exposure for an open approach to harvest bone from the anterior iliac crest can leave a scar 5 cm in length. Here the wound for motorized trephine harvesting shows that such harvesting is possible with a much smaller 1.5 cm long “stab” incision with reduced morbidity. (b) The motorized trephine is being guided by a propeller-shaped guide to help remove cores of bone from the anterior iliac crest. (c) A cancellous core of bone is being harvested from the anterior iliac crest. (d) Hematoxylin and eosin stained light photomicrograph of a harvested cancellous core showing all of the elements necessary for osteogenesis within the harvested graft material. There is an abundance of osteogenic and hematopoietic stem cells in the graft and a natural scaffold of cancellous bone.

Technique

The patient is prepared as above with the open approach but here the iliac crest can be approached through a stab incision as small as 1–1.5 cm for a motorized or hand-driven trephine, and stripping of muscle is not necessary.⁵¹ Pain, postoperative morbidity, and complications are less frequent than with an open approach² and the procedure can be performed as an outpatient⁶ or even out of the hospital in a surgical office.^{52,53}

Posterior iliac crest

Bone quality and quantity

If large quantities of bone are required, the posterior iliac crest provides a good source for most of the large maxillofacial defects,³⁸ excluding the cases in which microvascular grafts are needed. Both cortical and cancellous bone can be harvested, even though the majority of gain is cancellous (Fig. 23.13). Greater amounts of bone can be obtained from the

Fig. 23.13 (a) Patient in prone position for harvesting of bone from the posterior iliac crest. (b) A 12 × 3 cm corticocancellous block of bone harvested for major reconstruction as a non-vascularized graft from the posterior iliac crest. (c) Strips of cancellous bone can be further harvested from the posterior iliac crest donor site. (d) Harvesting of the posterior iliac crest can become a routine for the anesthetic staff, surgical staff, and the nursing staff. The patient is first anesthetized and intubated while in the supine position on a stretcher. (e) The patient is then “flipped” on to the OR table in the prone position with the face down. The anesthesia staff ensure that the airway is patent and that all tubes and monitoring devices are located satisfactorily before the patient is further prepared and draped. (f) The curvilinear incision is outlined once the harvest site is prepared and draped. Note the locations of the superior cluneal nerves (SCN) and the middle cluneal nerves (MCN) drawn on to the patient. (cont’d)

Fig. 23.13 (cont'd) (g) The incision is carried down through the superficial fascia and the posterior iliac crest is exposed. (h) Osteotomies can be made with a saw as shown or by using osteotomes and chisels. (i) The corticocancellous fragments are prepared for removal from the posterior iliac crest.

posterior ilium and the maximum obtainable bone approaches 90–100ml. Patients seem to tolerate harvesting from the posterior iliac crest better than from the anterior iliac crest site with less postoperative morbidity.^{41-45,54} This may be due to the fact that they convalesce lying with the full weight of their body on their wound, thereby causing less hematoma formation.⁵⁵

Technique

After the nasotracheal tube has been passed to secure the patient's airway, the patient is carefully turned from the supine position to the prone position in a slightly reversed-flexed position. All necessary areas of the face, pelvis, and thorax are supported to allow proper ventilation and the pressure areas are carefully padded to avoid any injury during the harvest of the bone from the posterior iliac crest.

After harvesting, the patient must be turned back to the supine position for the intraoral procedure. The anesthetist and surgeon must make sure that this is done safely. Because of repositioning, the bone graft harvesting and recipient site reconstruction cannot be done simultaneously which will lengthen the operation time.

The planned incision is first marked on the left or right posterior iliac crest following the appropriate anatomic landmarks: the spinous processes of the vertebra and the posterosuperior iliac spine and crest to avoid the cluneal nerves. A 5cm curvilinear incision is usually adequate to gain access to the iliac

bone. A long-acting local anesthetic with vasoconstrictor is infiltrated subcutaneously as well as subperiosteally. After allowing sufficient time for vasoconstriction, and local anesthesia to take effect, an incision is made through skin and subcutaneous tissue with a #10 scalpel blade. Sensory nerves at risk are the superior and middle cluneal nerves (L1 to S3). Using electrocautery dissection through the subcutaneous tissues, the posterosuperior crest is identified and the lumbodorsal fascia divided between the abdominal and gluteal muscles. A subperiosteal dissection proceeds, and the tissue is reflected laterally in the appropriate region to harvest the quantity of bone required for the procedure. Care is used to avoid the sacroiliac ligaments.

Following identification of this region, the required size of the graft is outlined, and using saws, osteotomes, or a bur, osteotomies are performed under copious normal saline irrigation. After the block is freed, further underlying cancellous bone may be harvested using a series of bone gouges and curettes. Once sufficient quantity and quality of bone have been harvested, all sharp bony edges are trimmed with a bone rasp. Bleeding points are then attended to, and the wound is then flushed with copious amounts of normal saline. The wound is then closed in layers: periosteum, lumbodorsal, dermis, and skin. At this point, the patient can then be carefully repositioned to the supine position on the operating table for the completion of the reconstructive part of the procedure.

Fig. 23.14 (a) The periosteum of the right fifth rib has been incised and the rib exposed. The costal cartilage has been incised on the medial aspect of the rib, taking care not to damage the underlying internal mammary artery. (b) A rib stripper is used to elevate the periosteum of the rib on its posterior aspect to prevent tears of the parietal pleura which could result in pneumothorax. (c) A rib cutter is in place to make the posterior cut through the rib without damaging the underlying structures of the mediastinum. (d) The harvested fifth and seventh ribs. Alternate instead of consecutive ribs are harvested when more than one rib is required for the planned reconstruction to avoid the possibility of a flail chest postoperatively. (e) A hypertrophic scar as a consequence of a rib harvesting. Unsightly scars are a possible complication of extra-oral harvesting approaches. They can be minimized by wound placement and closure techniques but they remain a possibility.

Costochondral grafts

Bone quality and quantity

Costochondral grafts are beneficial since both cartilaginous and bony tissues may be harvested (Fig. 23.14). The chondral part may be useful as an articular surface for temporomandibular joint reconstruction and provides a potential growth center for growing patients.⁵⁶ The bone, however, is limited by the size, curvature, and strength of the rib. In young adults the cartilage may calcify early and be disappointing when costal cartilage is sought for temporomandibular joint reconstruction. For reconstructing the temporomandibular joint, the contralateral rib

usually has the more favorable contour and reconstruction can be performed with a graft from the fourth to eighth rib. Ribs from either side can be harvested, but most surgeons prefer to use the right side over the left side because of the position of the heart. Indications for costochondral grafts include reconstruction of the TMJ in congenital malformations such as in hemifacial microsomia, and in acquired cases such as TMJ osteoarthritis or condylar fractures.⁵⁷ The disadvantage of using rib as the donor is a visible scar on the chest. In women, the incision can be hidden in the submammary crease. In addition to pain, some postoperative pulmonary complications such as atelectasis and, rarely, pneumothorax have been reported.

Technique

After the nasoendotracheal tube has been passed to secure the patient's airway, the patient may be prepared and draped for a two-team approach for this procedure. A curvilinear incision is used that corresponds to the submammary crease and will usually overlie the sixth rib. The skin is incised sharply and sharp dissection with periosteal elevators follows in order to enter the plane overlying the ribs from the midaxillary line to the costochondral junction. A longitudinal incision is made over the bony portion of the rib, and a careful subperiosteal dissection is performed with periosteal elevators circumferentially around the rib. Great care is used during the dissection of the inferior and deep aspects of the rib, to avoid the neurovascular bundle, and on the medial aspect of the rib, to avoid lacerating the internal mammary artery. Either saws or rib cutters may be used to harvest the costochondral graft with a variable amount of cartilage attached to the end. The cut edge of the remaining rib in the donor site is rounded with bone rasps to avoid sharp edges. Normal saline is placed in the donor site, and the patient's lungs are inflated to assess for a possible pneumothorax which

may require pleural repair or a chest tube. The wound is closed in layers and a long-acting local anesthetic with epinephrine may be administered to the donor site.

Calvarium

Bone quality and quantity

The cranium is composed of two layers of thick cortical bone, the outer and inner diploë. The cancellous bone in between varies in thickness. Calvarial grafts from the areas of the parietal bone are the most useful and the thickness of the bone should be at least 6.0 mm to consider *in situ* harvesting. Cortical membranous grafts consisting of 4 × 4 cm pieces of tissue 5 mm thick can be harvested,⁵⁸ but there is little cancellous bone available. This graft site is ideal for reconstruction of zygomatic or orbital defects when using cortical grafts. Particulate grafts may also be harvested with the use of a suction trap (Fig. 23.15).^{22,59} Postoperative morbidity is surprisingly minimal as long as a drain is placed to prevent hematoma or seroma formation. Intracranial perforations are rare.

Fig. 23.15 (a) A coronal flap is used to expose the bones of the calvarium. (b) A pencil outline is made on the skull for a planned outer table calvarial harvesting to reconstruct a deficient zygomatico-maxillary complex. (c) A large round bur outlines the harvested bone. The outline of the harvest with a groove made by the large round bur facilitates the harvest by allowing space for the oblique placement of an osteotome to eventually help lift up the zygoma-shaped bone graft as a single piece. (d) The osteotome harvesting the outer calvarial plate or diploë. (*cont'd*)

Technique

Following the induction of general anesthesia, the patient is prepared and draped for a craniomaxillofacial procedure. A dilute, long-acting local anesthetic with vasoconstrictor is infiltrated along the pre-planned incision line. The planned scalp incision can be coronal or hemi-coronal and is made above the hairline parallel to the direction of the shafts of the hair follicles in order to minimize the risk of alopecia. After allowing adequate time for the vasoconstrictor to take its effect, a sharp dissection with a scalpel down to the subgaleal fascia is performed. Clips are

then applied to the edge of the wound to control bleeding from the scalp. The dissection of the scalp flap should proceed in the subgaleal plane, and then the pericranium of the calvaria should be incised sharply. The planned area of the graft harvest is marked out with a bur, staying at least 2 cm from the sagittal suture to avoid overlying the sagittal sinus. A large round bur is used to make initial cuts through the outer cortex of the calvaria. A suction trap is continuously used to harvest particulate bone even when a cortical graft is harvested. The cuts are beveled to allow insertion of a curved osteotome in a plane parallel to the outer surface and at the diploic level.

Fig. 23.15 (cont'd) (e) The mobilized graft is then removed in one piece. (f) The resulting defect of the outer calvarial table. (g) A specially designed bone trap with valves to prevent both desiccation of the graft and minimize bone graft contamination (CSMT, Mississauga, Ontario, Canada). (h) The "blown-apart" components of the bone trap. (i) The suction trap was used while the large round bur was drilling through the outer calvarial diploë of the skull. The particulate bone graft which the trap collected would otherwise have gone to waste. This material can be used in further reconstruction of the the defect left by harvesting the outer table of the skull. (j) The particulate graft from the outer layer of the skull was used to reconstruct a frontal bone defect.

Once the graft has been harvested the donor bed is checked to assure integrity of the inner cortex, and a piece of gelatin foam is placed over the site. The periosteum is reapproximated and the scalp closed in layers, with the galea being reapproximated. The skin can be closed with either staples or sutures.

Proximal tibia

Bone quality and quantity

The proximal tibia is another important source of autogenous bone. A great deal of cancellous bone can be harvested even though the quality of bone in elderly patients is less predictable due to fatty deposition in the bone marrow (Fig. 23.16). Cancellous bone from tibia can be compressed and used in sinus lift-

ing and in alveolar augmentations. Equal amounts of bone are available from either lateral or medial approaches and up to 42ml of cancellous bone may be harvested.⁶⁰⁻⁶² For more extensive volumes of grafts, bilateral graft harvesting may be performed but may result in impaired early ambulation. Morbidity may include temporary gait disturbances, scarring, and fracture of the tibial plateau.^{63,64}

Technique

The proximal tibia has become popular as a bone graft donor site due to low morbidity and the fact that the operation can be performed in an outpatient setting under sedation and local anesthesia. The graft is usually harvested with the patient in the supine position. Harvesting is made close to Gerdy's tubercle,

Fig. 23.16 (a) A lateral view of the flexed knee showing the iliotibial band insertion. Gerdy's tubercle is located just inferior to this insertion. F represents the fibular head, immediately in front of the common peroneal nerve which must be avoided during this harvesting technique. T pinpoints the attachment of the ligamentum patellae into the tibial tubercle. (b) The incision below the iliotibial band is carried through the superficial fascia until the periosteum over Gerdy's tubercle is incised. (c) A circular osteotomy is performed through the lateral cortex of the tibia to permit access to the cancellous bone within the tibial metaphysis. (d) Generous quantities of cancellous bone are removed from within the tibia. (e) The empty tibia harvest site and wound just before closure.

which is clinically easy to find, about 4cm inferior and lateral from the knee's patellar bone.^{60,61,65} The planned 3cm longitudinal and slightly angled incision is marked on the skin overlying Gerdy's tubercle and a long-acting local anesthetic with vasoconstrictor is infiltrated subcutaneously as well as subperiosteally. After allowing sufficient time for vasoconstriction, and local anesthesia to take effect, an incision is made through skin and subcutaneous tissue with a scalpel. Sharp suprapariosteal dissection overlying and inferior to Gerdy's tubercle proceeds. This dissection should be medial to the tibialis anterior muscle and lateral to the patellar ligament. A cortical window is made with burs, saws, or osteotomes measuring 1 × 1 cm. A medial approach to the tibia may also be used to avoid the iliotibial tract insertion.^{62,66} In this approach, the landmarks are a vertical line drawn through the patella and tibial tuberosity, and the other perpendicular to the first, through the tibial tuberosity. It is recommended that an oblique skin incision be made centered over a point 15mm superior to the horizontal line and 15mm medial to the vertical line.⁶² Subperiosteal dissection continues along this incision and a bone window is made to harvest the cancellous bone with curettes. Alternatively, a small stab incision and a trephine may be used for smaller amounts of bone. The wound is then closed in layers. After harvesting, a tensor bandage must be applied to the knee and ambulation is encouraged immediately.

Proximal ulna

Bone quality and quantity

The upper extremity of the ulna has several sites of potential bone graft harvesting.⁶⁷ The posterior surface of the ulna just distal to the olecranon is one of them (Fig. 23.17). Cortical strips can be harvested, for nasal reconstructions, and the bone suitable for harvest in the adult is approximately 5 cm long and 1 cm deep and wide.⁶⁸ Cancellous bone volume is relatively unpredictable at this site but the morbidity is rather minimal. A tourniquet can be used to minimize blood loss. Postoperative pain at the donor site is usually much less than that experienced at an iliac crest donor site.

Technique

The operation can be performed in an outpatient setting under sedation and local anesthesia. The olecranon process is the bony protuberance of the proximal ulna palpable dorsally under the elbow skin. It is continuous as the subcutaneous border of the posterior ulnar bone, bounded by the insertion of the triceps and anconeus muscles, and the origin of the flexor carpi ulnaris muscle of the forearm. The non-dominant arm is usually chosen for harvesting the graft and a pneumatic tourniquet is applied to the arm. A

long-acting local anesthetic with vasoconstrictor is infiltrated subcutaneously as well as subperiosteally. After allowing sufficient time for vasoconstriction, and local anesthesia to take effect, a transverse incision is performed with a scalpel. A longitudinal incision is made in the periosteum and a periosteal elevator is used to strip the periosteum and the adjacent muscles. An oscillating saw or fissure bur may be used to cut through the cortex of the proximal ulna and the cortical graft is liberated with a curved osteotome. The cancellous bone can be harvested at the desired thickness with the use of osteotomes and curettes. Bleeding points are then controlled and the periosteum is closed with resorbable sutures. The incision is closed in two layers and a bandage is applied to the elbow after which the tourniquet is removed.

Vascularized fibula

Bone quality and quantity

A vascularized graft is an ideal choice in large defects or when the bone graft recipient bed has questionable vascularity. Patients with decreased vascularity, such as those who have received radiation to the head and neck area, may be at risk for future osteoradionecrosis. Patients with hypovascularity such as those with Raynaud's disease should be treated using a vascularized bone graft. The fibula is one of the most versatile sites for maxillofacial reconstruction requiring a vascularized bone graft (Fig. 23.18).

One major disadvantage of this flap is that the harvested fibular bone graft is tubular in shape and therefore not always the most ideal shape or form for grafting in the maxillofacial area. It has a dense outer cortex and a marrow space which is sparsely occupied by trabeculae when compared to the mandible.⁴⁸ Soft tissue may also be harvested together with the fibula and may be useful if there is a lack of soft tissue coverage for the graft at the recipient bed. The procedure is also very time consuming and the donor site morbidity may be significant: scarring and ankle instability are possible complications.

Technique

After the nasotracheal tube has been passed to secure the patient's airway, the patient is prepared and draped in the customary manner for a two-team approach to this procedure. The patient's hip and the knee are slightly flexed, and a pneumatic tourniquet is placed in the proximal aspect of the leg. A separate field is used to avoid cross-contamination of donor and recipient sites.

A line connecting the lateral malleolus to the fibular head is drawn. The dissection is carried down to the crural fascia that is subsequently incised. A 2–3 mm muscle cuff surrounding the bone is maintained. The dissection continues through the anterior border of the peroneal muscles. The extensor digitorum

Fig. 23.17 (a) Incision design on the posterior surface of the forearm distal to the olecranon. (b) The proximal one third of the posterior cortical surface of the ulna is exposed. (c) The cortical bone graft has been harvested from the posterior surface of the proximal ulna. (d) The 5 cm cortical strut harvested from the proximal ulna is useful for nasal reconstruction.

longus and the extensor hallucis longus are elevated anteriorly, exposing the interosseous septum between the fibula and the tibia. Next, two horizontal incisions are performed in the proximal and distal aspects of the fibula where the osteotomy is planned. The osteotomies to shape the fibula should be performed while the fibula is still pedicled to the proximal vessels in order to minimize the ischemic time. The vessels in the recipient site are prepared before ligation of the proximal aspect of the peroneal artery. The osteotomies are done in the donor site leg with a saw while a malleable retractor protects the medial aspect.

The distal aspects of the peroneal vessels are ligated and the vascular pedicle is carefully dissected superiorly to identify the branching of the peroneal artery from the posterior tibial artery. The graft is harvested together with the branches of the peroneal artery and its accompanying veins or venae committantes.⁶⁹ The donor site can be closed primarily or managed by the placement of a split-thickness skin graft. At the recipient bed, the graft is secured into position and the vessels are anastomosed to the superior thyroid, lingual, facial or superficial temporal arteries and branches of the internal jugular vein.

Fig. 23.18 (a) Lateral view of the leg with the outline of the fibula drawn on the skin of the leg. Note the branches of the posterior tibial and peroneal arteries. The potential accompanying skin paddle and its perforators are drawn in red. (b) The inferior aspect of the fibula has been osteotomized. Note the pedicle proximally. (c) A "closing wedge" osteotomy has been performed to allow the formation of a mandibular angle. The rigid fixation hardware has been applied to the fibula before the vascular pedicle is severed. (d) The fibula is ready for transfer to the recipient bed in the head and neck where its artery will be anastomosed to a branch of the external carotid and its veins to the facial or jugular venous network. Chapter 24

Treatment of Bone-deficient Ridges in Implant Rehabilitation

Karl-Erik Kahnberg

The chapter contains an overview of bone graft treatment in implant surgical rehabilitation. Aspects of bone graft behavior in the clinical situation, treatment of the bone graft, and discussion about particulated bone or bone block are included in the chapter. Use of the bone graft as an inlay graft or onlay graft is another important issue. Surgical techniques associated with bone grafting are also part of the chapter together with comments on the surgical split crest technique. The use of platelet-rich plasma (PRP) in connection with bone graft is discussed. Finally possible complications associated with different bone-grafting techniques are considered.

Introduction

Surgical techniques today enable us to reconstruct bone-deficient regions equally well in the maxilla and the mandible. Bone grafting techniques, using autogenous bone from the iliac crest, mandibular symphyseal region, mandibular angle or cranium, can provide material for reconstruction purposes. Onlay grafting is especially indicated for defects, thin ridges and as a complement to inlay grafting. Inlay grafting, in combination with orthognathic surgery, has a predictable outcome.

Background

Functional rehabilitation with dental implants has been in practical use for over 40 years with extremely good results.¹ Early long-term studies over 15 years, in rehabilitation of edentulous mandibles, show success rates of over 90%. Edentulous, resorbed mandibles were the most problematic situations and these were also where fixed implant bridge solutions were most indicated.² The long-term results have been remarkably good, which today means that it is possible to have immediate loading in most edentulous mandibles.¹ The maxillary region is more problematic, especially with regard to the anatomic situation, where the maxillary sinus and nasal cavity occupy large areas. The cortical structure of the bone tissue in the maxilla is not the same as in the mandible, due to factors such as muscle influence on the mandible. The fact that the mandible is the mobile part of the chewing system explains some of the differences between the two jaws. The edentulous maxilla may require much more augmentation than the edentulous mandible, in order to be suitable for implant rehabilitation.

Bone deficiency was considered a contraindication for implant surgery and rehabilitation. In the mandible, a reduced amount of bone could still be enough for implant success because of its cortical bone structure, but in the maxilla, inadequate bone volume was considered to make implant stability and success impossible.

Over time biomaterials of different kinds have been more extensively used with a satisfactory clinical outcome, although the healing time is at least double that for autogenous bone grafts. Other surgical techniques to solve bone-deficient situations, such as zygoma implants, are also available for this kind of patient. There is a spectrum of surgical techniques available today which enable us to solve all kinds of

bone-deficient situations, equally satisfactorily in the maxilla and the mandible.

Aspects of bone graft behavior

Autogenous bone graft material is the gold standard for reconstruction of bony defects in the facial skeleton, such as tumor resections, congenital defects or atrophy of the jaws.^{3,4} Fresh, immediately harvested bone graft is by far the most reliable.⁵⁻⁸ The bone graft may then be replaced by new bone by osteoconduction or by osteoinduction through surviving osteogenic cells.⁹⁻¹³ The microvascular system in the bone graft may also make minor anastomosis with the surrounding vital tissue and revascularize the graft material.¹⁴⁻¹⁶ The predictability of the graft volume has not always been certain. Postoperative resorption may radically reduce the volume by up to 50–70% of the graft when it is in a passive state. Several factors may be of importance in maintaining as much bone graft volume as possible. Recent literature reviews indicate that the embryonic origin is important for the graft survival. Membranous bone should be superior to endochondral bone with less resorption over time.¹⁷⁻¹⁹ The revascularization of the graft is extremely important for starting new bone formation. Another important factor in preserving bone graft volume is rigid fixation of the graft, probably because this creates an appositional phase earlier, and thereby promotes improved osteoconduction.²⁰⁻³⁰

The recipient bed for the bone graft may also be of importance for graft survival and volumetric changes. The influence of the bone graft recipient site on the survival of onlay bone grafts has been studied in several publications. The degree of contact between bone graft and recipient site as well as the orientation of the bone graft may have a significant effect on remodeling of vascularized bone grafts.^{31,32} Cortical preparations of the recipient bone marrow site allow exposure of osteogenic stem cells to the graft and may improve bone healing.^{33,34} Several publications support the theory that perforated bone is superior to unperforated. The perforations may increase initial healing of the bone graft, but there is no evidence that they help to maintain bone graft volume. Osteopromotive membranes have been used to improve bone graft survival and stability; these allow free diffusion of tissue fluid and prevent cellular ingrowth from adjacent connective tissue.

Membranes in combination with hyperbaric oxygen, growth hormones or bone morphogenetic proteins have been shown to increase the rate of bone formation. Bicortical bone grafts retain bone volume better than unicortical grafts. A major improvement in graft incorporation was observed following exposure of underlying recipient marrow through cortical perforations.^{35,36} The effects of marrow exposure by cortical perforations of the recipient bed resulted in a migration of the recipient bone marrow into the graft

as well as decreased loss of graft volume. A combination of cortical perforations of a bicortical graft and the host bed gave increased graft stability and corticalization of the marrow.³⁷ When the graft was covered by an osteopromotive polytetrafluoroethylene (e-PTFE) membrane, improved graft integration and greater size preservation were observed even after membrane removal.³⁵

However, full volumetric maintenance of the graft was not accomplished in any of these studies. A combined treatment of high concentration of recombinant human bone morphogenetic protein-2 (rh BMP-2) and membrane lead to a rapid and complete graft integration and pronounced bone formation resulting in maintained or even enhanced graft size. However, the use of high dose rh BMP-2 without a membrane resulted in loss of graft size, extensive bone resorption, and only small amounts of new bone formation.^{38,39}

Block or particulated bone

Bone block grafts are structurally stable and initially resistant to resorption. The autogenous bone block will be almost totally necrotic after the grafting procedure and needs revascularization to survive. Incorporation of the graft is initiated by an inflammatory reaction during the first weeks, which then turns into a granulation phase, followed by osteoclastic activity. The new bone in and around the bone block is formed by creeping substitution and development of lamellar bone. This process proceeds gradually and has not reached normal physiological strength until 1 year. Normal biological properties are not present for at least 2 years, and part of the block will still contain residual necrotic original bone. Mechanical strength will be reduced during the first year.

Particulated bone graft can be both cortical and cancellous. Particulation can be done with a bone mill or the bone can be cut into pieces with bone scissors. Cancellous particulated bone has a larger surface area exposed to the surrounding tissue and vascular ingrowth may proceed faster than in bone block grafts. Compared to cortical graft it regains biological properties faster but it is also more exposed to resorption activities. The cancellous bone graft gradually increases in mechanical strength and it takes 1–2 years to reach normal mechanical strength, much like the bone block graft.

Onlay grafting

Different methods for reconstruction of the atrophic maxilla can be used, depending on the actual situation. An atrophic alveolar ridge, with sufficient height but which is too thin, may be suitable for onlay grafting, where bone graft from either the hip or the mandible can be used for augmentation. Onlay grafting aims to widen the crest and make it possible for

implant insertion. It is very important not to reduce the vertical height of the crest, since vertical augmentation may be very difficult to achieve.

The first attempts to treat severely resorbed maxillae were made in the 1980s with large horseshoe-shaped bone blocks grafted to the maxillary ridge (Fig. 24.1). Technical difficulties with the technique made it unpredictable and there was a relatively high morbidity rate.⁴⁰⁻⁴⁸

The buccal onlay grafting technique is useful in the posterior mandible as well as in the maxillary alveolar process. To achieve as good a result as possible it is advisable to make small perforations in the buccal cortical bone before attaching the graft with plate screws. If there is a discrepancy between the graft and the host bed it is also advisable to put bone graft material in the space to optimize the contact between bone graft and crest. The bone graft may be harvested from the mandibular angle, chin region, iliac crest or cranial sites. The most important issues in this procedure are to achieve rigid fixation of the bone graft and to close the covering soft tissue in such a way as to prevent microorganisms from the oral cavity entering the grafted area. The flap covering the bone graft should have a relaxed position and not be

forced into a position by use of a strong suture. If this is not achieved, the graft may be totally destroyed due to wound dehiscence and compromised vascular blood supply.

A large onlay graft was the initial method of choice for reconstruction of the resorbed edentulous maxilla. The bone graft was obtained from the iliac bone beneath the iliac crest not involving the arch of the crest (Fig. 24.1a, b).⁴⁹ The horseshoe-shaped bone graft was modeled to fit on to the exposed upper jaw crest (Fig. 24.1b). The remaining, exposed crest of the upper jaw was ground to fit the graft better and the cortex was perforated with a small round drill to form a better vascular bed for the grafted bone. After modeling of the bone graft to fit on to the crest, implants could be inserted into the graft and retained in the residual crestal bone in a one-stage procedure; alternatively the graft could be attached to the crest with plate screws in a two-stage procedure, thus allowing the graft to become more vascularized before implant insertion. The choice of a one- or two-stage concept depends, of course, on the amount of available bone volume. More residual bone allows for a better and safer implant stability and is therefore more suited for one-stage procedures. Large onlay

Fig. 24.1 (a) Lateral radiograph of edentulous maxilla and mandible. (b) Onlay grafting with block graft from the iliac bone and simultaneous implant insertion. (c) Implant and bone graft in place. (d) Soft tissue closure. (e) Radiograph of implant placement. (f) Abutment connection 6 months later. (g) Implant-supported bridge construction.

block grafts have been shown to achieve a good result in long-term follow-up with one-stage implant surgery and also with a two-stage surgical technique.^{43,44,46,48,50}

Long-term clinical and radiographic follow-up studies have shown very good success and survival rates with onlay grafts with only minor drawbacks.

With all autogenous bone grafts, healing follows the same principles, according to Wolf's law. The bone graft has to be functionally stimulated in order not to be resorbed. So a bone graft without functional stimulation by chewing through implants will resorb more or less completely. This functional stimulation is very well achieved by the implants. One should always allow for some remodeling resorption where excess bone graft material will disappear.

Bone graft will always adapt to functional load and stimulation. Thus in the horseshoe-shaped iliac bone grafts with excess volume outside the implants,

functional remodeling, especially in a buccal–lingual direction was clearly evident. In patients with a retrognathic position at the upper jaw this resorption of 2–3 mm was negative since the retrognathic look of the maxilla was still noticeable even after implant surgery.⁴⁵

A technical problem of onlay grafting for small and larger surgical procedures is that the additional bone material has to be covered by a vital, vascularized flap, which must not be stretched or damaged. Careful closure of the incision without communication with the oral cavity is another important factor for a successful result. Big bone blocks for treatment of edentulous maxillae are especially vulnerable since there is so much foreign material to be incorporated within the tissue. Therefore it is of utmost importance to have as thick a flap as possible, with good vascularization to form a tension-free cover over the bone graft material (Fig. 24.1d).

Fig. 24.2 (a) Clinical view of thin but high alveolar crest in the anterior region of the maxilla. (b) Onlay grafts positioned to increase the width of the alveolar crest. (c) Soft tissue healing. (d) Bone graft healing. (e) Implant-supported bridge in place. (f) Panoramic radiograph after bridge construction.

Fig. 24.3 (a) Single tooth loss in the anterior maxilla. Thin alveolar crest. (b) Onlay graft in place to increase bone volume of the crest. (c) Implant insertion in the reconstructed crest. (d) Implant-supported crown in place.

The onlay bone graft can be attached to the residual crest with either the implants (one-stage procedure) or in a two-stage procedure with either plate screws or osteosutures. The choice of which technique to use depends on the clinical situation (Figs 24.2, 24.3).

Inlay grafting

In cases with an atrophic maxilla, bone grafting can be performed using orthognathic surgical procedures. Maxillary osteotomy Le Fort I with down-fracturing of the maxilla is an excellent method for augmenting the alveolar process. After mobilization of the maxilla it can be manually repositioned with the finger or carefully with Rowe and Killey's disimpaction forceps. The sinus membrane and the sinus recesses are carefully extirpated. The nasal mucosa should be intact or repaired to avoid contamination from the mouth or from the nose. Bone graft material is modeled to fit into the sinus recesses and nasal floor and secured with osteosutures. Normally five wire loops are sufficient to attach the bone graft of combined cortical plate and cancellous bone to the sinus recess and nasal floor. The maxilla is then held in its planned position with plates and screws. Anterior repositioning up to 10–15 mm is possible in most cases. Inferior repositioning can also be done to adjust the relationship between lip and upper jaw crest.

The Le Fort I technique for bone graft augmentation of the edentulous maxillas was originally introduced by Sailer who simultaneously performed grafting and implant installation.⁵¹ In the present model the bone graft is allowed to heal for 4–5 months before implants are installed. Implants can then be positioned as required for the prosthetic solution (Fig. 24.4). Slightly different approaches can be used for this procedure but the outcome with the treatment is usually very good with success and survival rates of 90–95%.^{52,54–60}

Preparation of the grafting site to optimize the healing process can be done by perforating the cortex of the recipient site with a small round bur. The cortical surface can also be roughened to stimulate bone formation. When pure cortical bone graft is placed against a cortical ridge the healing time should normally be extended 1 or 2 months to avoid the risk of inadequate healing between the two cortical surfaces.

The advantages with this method for treatment of deficient bone volume in the maxillary alveolar process are the predictable result and the possibility of correcting sagittal discrepancies between the jaws to some extent to improve the prosthetic possibilities. The problem with soft tissue closure which may arise in onlay grafting is not a problem in inlay grafting.^{57,58,61,62} The choice between one- or two-stage procedure as well as early loading is up to the surgeon.^{63,64} The author's own experience suggests a

Fig. 24.4 (a) Panoramic radiograph of severely resorbed edentulous maxilla. (b) Maxillary osteotomy with interpositional bone graft. (c) Reconstructed maxilla with bone graft from the iliac bone. (d) Panoramic view of bone graft reconstruction. (e) Implant surgery at a second stage 4 months later. (f) Implant-supported bridge in place.

two-stage procedure with bone graft healing for 4–5 months and implant healing for at least 3–4 months (Fig. 24.2).

Bone graft reconstruction of the jaws before implant placement

Surgical incision and flap technique are of utmost importance for obtaining a positive result for a grafting procedure. If possible the incision line should not be placed over the bone graft, but preferably in the vestibule to avoid contamination of the graft from the incision line. The relaxation incisions should also be placed away from the grafted area and should allow closure of the incision without tension or gaps. The flap should not be stretched at the time of wound closure, as this results in immediate constriction of the vascular supply and subsequent bone graft exposure.

The flap should be as thick as possible: a larger vascular net in the flap gives a better chance of revascularization of the bone graft. Preparation of the graft site is also important for healing and for the rate of bone graft integration. If the recipient site is cortical it

can be an advantage to make some small holes in the surface with a round bur. The contact area between bone graft and recipient site should be as good as possible to facilitate bony union. Smoothing the contours of a bone graft block with a drill to avoid sharp edges or spicules is necessary to avoid perforation of the mucoperiosteal flap.

The bone graft block should be fixed with plate screws of varying length, however overlong screws should be avoided, as these may perforate bone and mucosa on the opposite side. Osteosutures may also be used as retention devices. When particulated bone graft is used a resorbable or non-resorbable membrane may be inserted to keep the bone graft material in position. When using both resorbable and non-resorbable membranes, it is extremely important to have a water-tight flap closure over the region in order to avoid contamination from the oral cavity into the graft region. A non-resorbable membrane is removed at the time of implant placement. Resorbable membranes do resorb within 3–4 months, i.e. about the same length of time as for bone graft integration. If particulated bone is being used, the mucoperiosteal flap can serve as a membrane; the flap is raised no more than is absolutely necessary so there is a pouch

to fill with particulated bone or biomaterial. In these cases relaxation incisions are not required.

The healing time for onlay grafts and inlay grafts is between 3 and 6 months. Dense cortical bone graft material takes longer for bone integration. If the surgical approach into the grafted area is made too early there is a risk that the bone graft will come out and the whole procedure will have to be done again.

With particulated bone graft there is a risk that resorption will remove parts of the graft if one waits too long. Ideal times for cortical bone grafts are between 4 and 6 months and for spongy particulated bone grafts between 3 and 4 months. Healing time for biomaterials like Bio-Oss[®] granules are at least 6–9 months. If the Bio-Oss[®] grafted site is approached too soon, there will only be loose Bio-Oss[®] particles and the procedure will have to be performed all over again. When using Bio-Oss[®] or similar biomaterial, a biological membrane like Bio-Gide[®] or similar can be used to collect and concentrate the granules; the flap is then carefully repositioned and closed to form a water-tight seal, otherwise inflammatory reactions may occur and jeopardize both the graft material and part of the original crest.

Grafting procedures as a whole demand surgical skill and experience both in obtaining the graft material from different regions (see Chapter 23) and in preparing the graft site and handling of the bone graft material. If these procedures are not performed well, the risk for failure is obvious.

Avoiding crestal incisions in bone grafting procedures is not always possible but when there is an opportunity to do a vestibular incision and raise the flap over the crest, enabling total closure over the bone graft block, it is a clear advantage. However, this technique is not always possible or practical and then a mucoperiosteal flap must be used, which is lengthened by periosteal cutting at the base of the flap to ensure a tension-free flap when closed.

Use of platelet-rich plasma

The use of platelet-rich plasma (PRP) in connection with bone grafting was introduced by Robert Marx in 1948.⁶⁵ He used a concentrate of platelets when doing cancer reconstruction cases. The theory of getting a concentrate of platelets into the wound area is to concentrate bone morphogenetic proteins, bone morphogenetic enzymes, and immunoglobulins as close as possible to the bone graft material in order to enhance and speed up the bone regeneration and bone integration processes.

Later studies with both animals and humans have not been able to confirm the effect on bone regeneration. However, a markedly noticeable effect on soft tissue postoperatively has been observed. Concentration of enzymes and immunoglobulins may reduce the initial inflammatory surgical response and therefore result in a less pronounced inflamma-

tory postsurgical reaction. Human grafting studies by Thor and co-workers do, however, suggest that there may be a slight adjunctive effect of PRP on bone healing and bone regeneration, especially in conjunction with use of implants which have a moderately roughened implant surface.^{50,66–69} Further studies will be needed to verify the benefit of PRP in bone grafting cases.

The reason for the limited effect on bone graft healing could be that PRP releases enzymes and bone morphogenetic proteins with a very brief action time span, while bone regeneration is a slow process with a time span of weeks and months. Once it is possible to have slow-releasing adjuvants or surfaces on implants to allow for slow release of enzymatic substances, there may be a dramatic change in the effect of PRP and related substances. Until then it is advisable to reduce surgical time both in the bone graft harvesting and positioning and modeling of the bone graft, in order to maintain the graft's vitality. In a cortical bone graft block there will be a gradually "creeping substitution" of capillaries to vitalize and build up the new bone from inside and outside.

Staging of grafting procedures

Bone grafting by use of autogenous bone graft material can be done in one- or two-stage procedures. A one-stage procedure means that the implants are installed at the same time as the grafting procedure. A two-stage procedure means that one waits for healing of the bone graft before placing the implants.⁷⁰ In a one-stage procedure the outcome of the implants depends on revascularization and vitalization of the bone graft before osseointegration can occur.⁷¹ Experimental studies have shown that there is a slow phase in bone-implant contact in the bone graft area compared to in normal non-grafted bone tissue. The implants will depend on the residual bone tissue for primary stability and osseointegration before the bone graft gets enough microcirculation and living cell population for the osseointegration process. If the primary stability in the residual bone is too poor or the naturally occurring remodeling process due to the surgical trauma impairs the primary stability, there is a big risk of failure of the implant. The matter of immediate or early loading of the implants also depends on the initial stability and on the loading forces. Immediate or early loading can provide stimulation for the osseointegration process but may also be a disaster if the balance between stability and loading is negative.

Split crest surgery

An option already discussed for reconstruction of the alveolar crest which is too thin for implant placement is the buccal onlay graft, which will enlarge and

thicken the crest thus enabling implant placement. However, if the anatomy is suitable for splitting of the crest, i.e. two cortical layers and an intermediate marrow space, it may be possible to split the crest in the middle and place bone graft in between the two plates. If the alveolar crest is composed of only cortical bone there is a big risk of fracturing and destroying the crest. The incision should be made on the alveolar crest top, with minimal exposure of the bony surfaces on either the palatal side or the buccal side, so that the circulation to the two bony plates is not jeopardized. An osteotomy can be carried out with a chisel, oscillating saw or Lindemann drill to get the right direction. The two bony pieces are then separated with a chisel and the buccal bone segment with attached soft tissue fractured out of the base of the alveolar process. Particulated bone or Bio-Oss® can now be placed adjacent to the implant and the soft tissue closed. The procedure may be most successful in cases where there is a possibility of placing thinner implants without splitting the crest. However, in those cases where there is an indication for split crest surgery, the method has proven to be successful. If the crest is split in pieces a more complicated grafting procedure has to be done.

Complications

Complications may arise due to inadequate coverage of the graft or flaps which are stretched too much, with compromised vascular circulation. Exposure of the graft may result in loss of part or all of the graft. Smoking may seriously affect graft healing since capillary sprouting is reduced by nicotine.

Wound dehiscence problems may be the most frequent complication, since healing contraction may disrupt the wound. That is why it is so important to have a flap which covers the surgical area without tension. Stretching of the flap to close the wound may impair healing due to strangulation of the small vessels and capillaries. Wound dehiscence in the early stage of healing is mostly located in the incision line; however, in later stages after several weeks of healing, dehiscence may appear where the vascular supply is inadequate to supply and revascularize the bone graft material.

In early dehiscences there is a big risk of losing the bone graft totally and contamination from the oral cavity will make a reclosure almost impossible since the bone graft has already been contaminated. When the dehiscence occurs at a later stage, when a major part of the bone graft has been incorporated by revascularization and regeneration of bone, the problem is more limited to the actual area of exposure. The part of the bone graft which has been exposed and devitalized can gradually be removed and secondary healing will close the dehiscences over vital bone tissue.

Inlay grafting is performed with extremely thin maxillae, so there is always a risk for fracturing of the

palate or the sinus walls. It is possible to repair fractures by use of bone graft but it may be difficult to advance the maxilla once it has been fractured. Sinus infection can occur but is not a common complication.

Chapter 25

Implant Rehabilitation in the Posterior Maxilla Using Autogenous Bone Material

Karl-Erik Kahnberg

The chapter contains descriptions of techniques for bone augmentation in the posterior part of the maxilla by use of autogenous bone graft material. The morphologic and anatomic aspects of the maxillary sinus area are described in the first part of the chapter. Bone graft harvesting from different regions depending on the volume needed is briefly commented upon. The surgical techniques for sinus lift procedures with autogenous bone graft material in partially edentulous cases as well as single tooth cases are described. Alternative surgical solutions, like the impaction technique, are also included in the chapter. Finally possible complications that may happen in the sinus lift procedure are covered.

Complications associated with sinus lift procedures, 421

Introduction

For a long time the sinus lift procedure has been the solution for implant rehabilitation in the posterior maxilla with a limited amount of bone below the sinus cavity. Sinus lift involves opening a bone window to get access to the sinus cavity and gentle lifting of the sinus membrane, thereby creating a space for graft material. There are several surgical modifications and methods for the procedure but the aim of all of them is to increase the amount of bone for implant integration.

It is extremely important to keep the sinus membrane intact when it is elevated in connection with bone graft inlays. Since the drainage from the maxillary sinus is effected only through the osteum, a small canal leading out in the nose below the second nasal

concha, there is a huge risk that infections established in the maxillary sinus cavity with minimal drainage will be very severe. As soon as bony fragments or salivary products gain access into the sinus cavity there is a risk for sinusitis development. A massive sinus infection will drastically reduce the chance of inlay grafts surviving and thus prevent anchoring of implants.

If the available amount of bone volume below the sinus cavity approximates 10–15 mm there may be no need for a sinus lift procedure. It is therefore important to have determined the bone volume preoperatively by tomographic measurements or computed tomography (CT) evaluation.

Background

The technique and idea of reconstruction and augmentation of the alveolar crest within the sinus cavity was originally introduced by Hill Tatum in the 1970s.¹ His idea of the window technique has since then been approved and used worldwide.^{2–18} Invasive surgery into the maxillary sinus cavity has not always been successful. Perforations of the sinus membrane in connection with extraction could result in sinus fistula and sinus infection. Dislocation of a root into the sinus cavity would lead to a massive sinusitis unless treated. There is potential for inflammatory reactions in the maxillary sinus since the cavity is a closed space with very limited drainage capacity: the osteum is the only site of drainage and it is small. These circumstances inevitably make the sinus lift procedure sensitive, since it is of utmost importance to keep the sinus membrane intact to avoid any complication of graft or biomaterial going into the sinus cavity causing inflammation. The space to be used for implant rehabilitation is normally just a small part of the total volume of the maxillary sinus. With careful surgical technique and avoiding membrane perforations, the

results have been encouraging as reported in a massive literature.^{19–29}

The modern type of implantology focused initially on rehabilitation in the edentulous mandible. Removable dentures were most problematic in the lower jaw, where there were difficulties in achieving good retention. When implants were developed the initial area of use was the lower jaw. The results of the screw-type implants of the Brånemark type have shown excellent results in the lower jaw for more than 40 years. However, in the upper jaw it is often more problematic because there is more spongy and less cortical bone. Furthermore the hollow structure of the maxilla, with maxillary sinus and nasal cavity, reduces the bony base for implant surgery. As long as the alveolar processes maintain a decent volume both in height and width there is a good opportunity to install implants.^{30–40} However, if the residual bone volume beneath the maxillary sinus and nasal cavity is too small to provide anchorage for dental implants the alternative is to augment the residual bone volume either by onlay grafting or inlay grafting. Inlay grafting using the maxillary sinus recess or the nasal floor below the sinus membrane and the nasal mucosa, respectively, is a possibility for ridge augmentation. The techniques have been named sinus lifting and nasal lifting procedures, respectively. The maxillary sinus and nasal cavity occupy a large space in the midface and expansion of the sinus cavity down into the alveolar process often occurs in conjunction with tooth loss. The most logical augmentation for implants is the inferior part of maxillary sinus and sometimes also the nasal cavity by inlay grafting. With this type of augmentation the vertical height of the alveolar process will not be affected which may be a slight disadvantage, but the bone graft will be surrounded by bony walls of the sinus recess.

Current understanding is that the sinus membrane is not osteogenetic, so just lifting the mucosa does not produce more bone, otherwise the sinus cavity would be filled with bone. It is utterly important to keep the sinus membrane intact when it is elevated in connection with bone graft inlays to avoid sinus infection.^{41,42}

Morphologic aspects

The maxillary sinus in the newborn infant is only a small invagination in the middle concha. With time it expands into corpus maxillae and with some variations fills out the maxillary bone. The border zones are superiorly towards the orbita, medially to the nasal cavity, posteriorly towards the pterygopalatine fossa and infraorbitalis, inferiorly towards the alveolar process and laterally to the zygomatic process. The maxillary sinus drains through the ostium which is situated in the middle concha region. The ostium is located at the top of the maxillary sinus; sometimes there may be one or two accessory openings. The

deepest point of the maxillary sinus is normally located in the molar tooth area. Root tips of molar teeth and sometimes also premolars may project up in the sinus cavity covered only by very thin bone and by the sinus membrane, also called the Schneiderian membrane. The sinus membrane is in contact with the breathing air and also acts as a biological membrane with immunological properties like the nasal mucosa, but to a lesser degree. The membrane is multilayered, with cylindrical ciliated epithelium on the surface and an underlying basal membrane similar to periosteum. Mucus cells in the epithelium produce liquid that keeps the membrane moist and protects the ciliated epithelium. Seromucous glands with mainly serous secretion can be found in the sinus membrane. The transport capacity of the ciliated cells is limited to minor particles like dust but not larger ones like bone graft particles and root fragments. Damage to the ciliated epithelium results in partial or total stop in secretion and removal of minor particles.

The maxillary sinus in the adult can vary considerably in size and there is a continuous extension with increasing age. Expansion of the maxillary sinus into the alveolar process is especially observed in connection with extraction of molar teeth and also premolar teeth. Edentulism creates a situation where finally only a paper thin bony wall exists between the oral cavity and the sinus cavity. The maxillary sinus cavity is usually one big solitary cavity but it may also sometimes be divided into smaller chambers separated by septa. The origin of these septa may be a consequence of the sinus going deeper in the molar region and thereby forming septa towards the anterior part. The maxilla has a dense vascular network. The maxillary sinus is supplied by branches from the maxillary artery via the infraorbital artery and the greater palatal artery and the facial artery. Venous flow is via the sphenopalatine vein, the pterygoid plexus, and the facial vein. There seems to be a connection between reduced vascularity and atrophy of the alveolar process. Loss of the maxillary teeth and increasing age result in marked reduction in the vascularization of the alveolar process.

Surgical technique

The lateral window technique is by far the most frequently used surgical procedure (Fig. 25.1). The lateral window gives access to the sinus cavity and enables positioning of graft material. The buccal windows are made by a round bur, diamond bur or piezoelectric surgery for gentle removal of bone over the sinus membrane. All possible precautions should be taken to avoid perforation of the sinus membrane. The smooth touch technique is recommended in approaching the sinus membrane. The window may be infracted, in which case the superior part of the bone incision is only part way through the buccal bone. Alternative

options are to loosen the window but still have it attached to the sinus membrane, or remove the window completely and use it as a free graft (Figs 25.2–25.4). The sinus membrane is carefully elevated with a blunt instrument from the bottom of the sinus cavity. It can be difficult to elevate, especially if extractions have been performed recently, causing a tight connection with the sinus membrane (Figs 25.3, 25.4).

Another critical point is in the superior corner of the window where the infraction technique is used. The infraction may give rise to sharp contours which may easily cause perforation of the sinus membrane. If the perforation is very small a resorbable membrane (Bio-Gide®) can be used to cover the perforation. If the membrane is manipulated or wrinkled too much, trying to suture it, to cover the perforation, there is a clear risk that the perforation will be enlarged and destroy any chance of sinus lifting augmentation. Complications like sinusitis may occur if there are loose particles within the sinus cavity.

Bone graft material can be obtained from the iliac bone, cranial bone, tibial bone or mandibular bone. Small amounts of bone material can also be obtained by use of the bone collectors like Bone Trap® or safe scraper (Fig. 25.5). The amount of bone needed depends on the type of procedure. Bilateral sinus lifting for rehabilitation of the premolar and molar

regions demands a large amount of bone graft material, whereas for unilateral sinus bone graft, material from the mandibular angle or chin is enough. Sinus lift for single tooth replacement needs even less bone graft material.

The bone graft material from the mandible is mainly cortical, as is cranial bone graft, whereas bone graft from the iliac bone and tibial bone consists of cancellous bone material. Cortical bone graft is more resistant to resorption but normally a mixture of cortical and cancellous bone graft is used.

The bone graft material, either in cortical block or particulated bone, is placed below the sinus membrane in the inferior chamber of the sinus cavity. Depending on the clinical situation the graft material can be immobilized with wires, plate screws, or it can just be packed below the sinus membrane. It is important to ensure that the bone material is stable and not moving around. A piece of cortical bone can be used as a roof for the particulated bone which is collected in the sinus inferior recess. The bone can easily be immobilized with wire osteosutures or plate screws. The surgeon may choose to use a resorbable membrane to cover the bone graft. In a two-stage procedure the bone graft is normally left to heal for at least 4 months. Shorter healing time will risk failure of the bone graft; if the healing time is too long, resorption of the graft will begin. The question of whether to do

Fig. 25.1 (a) Sinus lift by use of the “window technique”. A lateral bone “window” is created using a round bur. (b) Infraction of the buccal window. (c) Sinus membrane is lifted and a space is created below the window and the sinus membrane. (d) Bone graft is positioned in the lower part of the sinus cavity and kept in place by the implants (one-stage surgery). (e) Bone healing after 6 months. (f) Implant-supported bridge in place.

Fig. 25.2 (a) Sinus lift by use of a two-stage technique. Bone window is removed and sinus membrane is lifted. (b) Space for the bone graft is created in the basal part of the sinus cavity. (c) Cortical bone graft is positioned as a roof in the basal part of the sinus cavity. (d) Particulated bone graft is placed below the cortical “roof” and secured with wires. (e) Radiograph of implants in the sinus graft. (f) Implant-supported bridge.

the bone grafting and implant placement in one or two stages is still open to discussion and needs more clinical scientific follow-up and analysis.

It is extremely important to have enough bone volume below the sinus cavity when doing one-stage surgery, attaching the bone graft with implants. Bone graft and implants have to be stabilized rigidly and even resist some reduction of marginal bone level and the grafted bone in the postoperative remodeling phase. If the alveolar bone below the sinus cavity is too thin (<5–6 mm) there is a high risk that the implants, together with bone graft material (blocks or particulated), become mobile with subsequent failure of the implants and the bone graft. However, in cases with more bone volume available in the alveolar process the one-stage technique can be suitable. Primary stability should be enough for one-stage surgery when there is 5–10 mm of residual bone volume in the alveolar process.

There are many opinions on immediate or early loading of the implants placed in grafted bone. If the residual bone volume in the alveolar process below the maxillary sinus is qualitatively and quantitatively sufficient to stabilize the implants and give them an initial primary stability ($R_f \approx 60$) it is possible to use early loading. The maxillary bones, however, are not often of good enough quality for immediate loading. Immediate or early loading can have a stimulating effect on bone healing and osseointegration, depend-

ing on the extent of loading and the primary stability of the implants. However, even with resonance frequency measurements (RFM), which give the surgeon an idea of primary stability, it is difficult to know whether immediate loading will be appropriate in individual cases.

Sinus lifting procedures using an impaction technique were originally presented by Summers.⁴³ The purpose of this technique is to initiate a split of the alveolar crest between the inner cortical part towards the sinus cavity and the outer cortical part (towards the crest).^{44–46} The residual bone in the alveolar crest should be at least 6–7 mm and contain both cortical bone and marrow to be suitable for the impaction procedure. The intention with Summer’s impaction technique is to fracture the cortical bone underlying the sinus cavity in such a way that the sinus floor can be elevated without rupturing the sinus membrane.⁴⁴

The procedure begins with flap elevation then preparation of implant sites with a round bur and spiral bur, but only through the cortical bone and slightly into the spongy bone (2–3 mm). The subsequent surgery is done with osteotomes which normally have the same diameter as the implant surgery drills. By gradually enlarging the implant site with osteotomes up to the desired length and width the implants can be installed without perforating the membrane. Usually the best result is obtained with

Fig. 25.3 (a) A case with a large sinus cavity and minimal residual bone volume. (b) The same case after sinus lift and bone grafting. (c) Tomograph in close section of the posterior maxilla before grafting. (d) Tomograph after sinus lift and bone grafting. (e) Clinical view of implant-supported bridge in place. (f) Radiograph after implant rehabilitation.

two to three implant sites in a row to be able to induce the sinus floor fracture. With only one implant site it is more difficult to achieve the same sinus floor elevation. The effect with only one impaction site may be very limited and the risk of sinus membrane perforation increases. In indicated cases, sinus impaction is a less demanding procedure for the patient, but still with predictable results.⁴⁴⁻⁴⁶ The choice of filling the space below the elevated sinus floor with bone graft or biomaterial is up to the surgeon. However, it is important to check for eventual perforations in the sinus membrane. Healing time after impaction and implant installation should be a little more extended than for conventional implant surgery.

In cases of single tooth replacement in the posterior maxilla where the available bone volume is too small to allow for conventional implants, a modified kind of sinus lift can be made. Where the sinus cavity has expanded down into the alveolar process after tooth extraction there is an ideal situation for a local sinus lift (Fig. 25.5).⁴⁰ A crestal incision is made in the edentulous area and connected with diverging relaxation incisions in the vestibule. A circular area over the sinus cavity bone is removed to the sinus membrane and the bone material collected with a bone collector during the preparation. The sinus membrane is carefully lifted and the implant installed through the crestal bone by standardized technique. The implant is allowed to penetrate into the sinus cavity below the

sinus membrane about two to three times the residual bone volume. The sinus membrane is thus held up by the implant which acts as a tent pole for the membrane. The bone material is placed around the exposed part of the implant but no attempt is made to completely fill the space around the implant. Recent results indicate a predictable outcome of the method.

The most frequent complication associated with sinus lifting procedures is perforation of the sinus membrane with maxillary sinus infections. Drainage from the sinus cavity is very limited with only the osteum as a natural canal, so there is a high risk for sinusitis after perforation with graft material moving around in the sinus cavity. Sinusitis must be treated with antibiotics and, often, the sinus must be reopened and cleaned, maybe removing part of the graft material. Dislocation of an implant into the sinus cavity may also occur which demands exploration and extirpation. Complications like lack of osseointegration, as in conventional implant surgery, may also occur. The complications in sinus impaction surgery are also connected with perforation of the sinus membrane and dislocation of graft material.

Literature review

There has been a large number of publications during the last decade regarding the outcome of sinus lift

Fig. 25.4 (a) Missing teeth in the left posterior maxilla due to periodontitis. (b) Panoramic view of the case. (c) Primary phase of sinus lift and bone reconstruction. procedures. Both retrospective and prospective type studies have been made regarding the outcome and results from varying periods of follow-up. One-stage surgical protocol, two-stage surgical protocol, and immediate loading results have been published.

The presurgical conditions may not always have been clearly defined which makes it a bit difficult to evaluate the impact of the bone grafting in the osseointegration process.

The reports in the literature about complications with sinus membrane perforations and subsequent treatment and treatment outcomes have been relatively few. However, the quality and thickness of the sinus membrane may vary quite a lot and the very healthy membrane can be extremely thin and consequently very vulnerable to a surgical approach. Repair of the membrane by suturing is not possible with the normal healthy ultra thin membrane but could eventually be made with a chronically affected thicker sinus membrane. The use of resorbable membranes like Bio-Gide® is a possible solution to cover small perforations in the membrane since the collagen material sticks to the membrane and may be an effective seal. Modifications of the conventional sinus lift procedure using particulated bone graft, cortical bone blocks or different kinds of biomaterials have also been reported in the literature.

Experimental studies both in animals and humans trying to lift the sinus membrane with the implants (implants acting as tent poles) and just collecting blood coagulum or blood with additional platelet-rich plasma have given some bone augmentation.⁴⁷⁻⁵¹ Long-term studies of the outcome by use of these methods are still not available.

There are numerous publications on sinus lift procedures either one or two-stage techniques, with immediate or delayed loading and with different kinds of grafting materials. Most studies present with a success and survival rate of between 90 and 97% with few exceptions. The method is well documented and generally has a predictable outcome. Sometimes the residual bone volume could have been enough for conventional implants, especially the short implants recently described. Long-term follow-up of the different solutions for implant rehabilitation in the posterior maxilla will evaluate which method is the most reliable and also indicate when and where we should be using the different techniques. Clinical and experimental studies will provide recommendations in due course.

Complications associated with sinus lift procedures

The sinus lift procedure is not without problems. Due to the anatomical situation with a large hollow space

with a minimal drainage via the osteum, infections may very well arise without proper drainage. Complications may happen during the operation with perforation of the sinus membrane during careful dissection and lifting. Small perforations can usually be repaired by use of a collagen membrane like Bio-Gide®, however larger defects more than 5 mm can be problematic in some cases and make the procedure impossible. Suturing of the sinus membrane has been suggested, but it is absolutely impossible with a healthy membrane which is thin like a soap bubble; it could sometimes be possible where there is a chronically inflamed and thickened membrane. When a bone graft block is used some authors claim that a perforation is not a risk factor for sinusitis, but that particulated bone graft is more prone to initiate inflammation if bone particles are moving around the sinus cavity.

Obstruction of the osteum prevents normal drainage of the maxillary sinus and should be avoided.

If a sinus infection occurs postoperatively it is of utmost importance that it is treated early in order to avoid a massive inflammatory reaction with obliteration of the sinus cavity and suppuration. Usually graft material or biomaterial particles have entered the large sinus cavity via a perforation. Access for evaluation, and drainage of the sinus cavity, are limited. It may even sometimes be necessary to make a naso-antral passage below the inferior concha in the nasal floor.

Bleeding in the sinus cavity is not desirable, since the blood clot may be a source for infection. The postoperative complications that may occur include wound dehiscence due to swelling and mechanical forces on the suture line. Signs of infection may appear during the first two postoperative weeks but can also occur at a later stage during the healing period.

Actions which can influence the intrasinus air pressure, such as sneezing, blowing the nose, and even drinking through a straw, should be avoided as much as possible as they may create a negative intrasinus pressure which can jeopardize the membrane healing process.

Implant failures may appear at an early stage within the healing period but usually the lack of osseointegration is noticed at the abutment connection. Temporary denture wearing should be avoided during the first two postoperative weeks in order to let the soft tissue incision heal before prosthetic loading.

As with other procedures involving use of bone graft material, smoking is a negative factor for the healing process due to nicotine's interference with the capillary growth during the microvascularization of the bone graft. Heavy smokers should be advised to stop smoking for at least 6 or even up to 9 months prior to the operation.^{51,52}

Chapter 26

Biomaterials for Bone Replacement in Implant Surgery

Carlo Maiorana

The chapter is a comprehensive overview of biomaterials which can be used as grafting material in the jaws. Different criteria for a biomaterial to be used in the human body are listed. The biomaterials most used in osseointegration are then described in detail. The different surgical situations where biomaterials can be used are presented, including postextraction sites, horizontal defects, vertical defects, sinus elevation and reconstruction in major, advanced osseointegration. Finally there is a section on the possible role of growth factors and bone morphogenetic proteins (BMP) in the integration of biomaterials.

an alteration of the intermaxillary relationship which is not compatible with prosthetically guided implantology. As for other areas, bone augmentation procedures can be performed prior to placement of the implant, concurrent with implant placement, or subsequent to it.

Up to 10 years ago, autogenous bone was considered to be the gold standard in the reconstruction of atrophic areas of the jaws, due to its osteoconductive, osteoinductive and regenerative properties; it should still be chosen as the most suitable material in severe atrophies (class V and VI according to Cawood and Howell¹). In the treatment of smaller defects (class III and IV), bone substitutes of synthetic and xenogenic origin have been playing an important role in implant surgery. All those materials, generally called “biomaterials”, are able to favor the adherence of cells and tissue regeneration thanks to a variable degree of osteoconductive activity; after being tested for several years through randomized prospective or retrospective studies, they can be considered as a reliable way to rebuild bone.

Something fundamental is to remember that the difficulty in rebuilding a bone defect is more related to its extent than its depth. In other words, a very deep but localized defect is easier to treat than a superficial but extensive one. Careful preoperative analysis of the site to be regenerated is important instead of deciding at the time of surgery.

Introduction

When bone reconstruction of the posterior atrophic maxilla is needed, different surgical procedures can be used. Following the loss of teeth, alveolar ridge resorption leads to a combined vertical and horizontal reduction of the bony support, at the same time increasing maxillary sinus pneumatization. Such a condition makes implant placement impossible, either because of insufficient vertical bone volume or

Biomaterials

The term biomaterial generally indicates any substance used to create a medical device destined for diagnosis, prevention, control, mitigation or therapy of a human disease, on condition that it persists in the body for at least 30 days after implantation. First of all, cytotoxicity, genotoxicity, and hemocompatibility of a biomaterial have to be evaluated. After that,

attention has to be paid to its macrostructure and microstructure, by evaluating the isotropy. Finally, its mechanical, physical, and chemical properties should be taken into consideration. Which characteristics should a biomaterial have to be considered for implantation in the human body? They can be summarized as follows:

- non-carcinogenic;
- non-antigenic;
- hydrophilic;
- radiopaque;
- easy handling;
- versatile (usable in several clinical fields).

Biomaterials can be obtained from the patient (autogenous), from beings belonging to the same species (homologous), from beings belonging to different species (xenogenic) or from minerals (alloplasts). Apart from autogenous bone, which has osteoconductive, osteoinductive, and osteoproliferative properties, and homologous bone, whose properties are mainly osteoconductive and slightly inductive, all the biomaterials used for bone regeneration are only osteoconductive scaffolds. Bone substitutes were created in order to promote bone regeneration, avoiding the necessity of harvesting bone from the patient. The first materials on the market were represented by ceramic hydroxyapatite of different macrostructures (coral, bioglass, ceramic hydroxyapatite) and the osteoconductive potential, and the resorbability, were not excellent with regard to the implant field. A few years later, demineralized freeze dried bone allograft (DFDBA) from human donors was introduced in the US; osteoinductive properties were claimed for this, because the demineralization process was able to expose bone morphogenetic proteins (BMP). In addition, some publications confirmed an osteoconductive property for this material.²⁻⁴ Unfortunately, the properties of DFDBA were not confirmed by later histologic and clinical studies in sinus elevation and guided bone regeneration (GBR) procedures.

At the same time, xenogenic anorganic bone was obtained from cattle,⁵⁻⁷ followed by similar materials from equine or porcine sources. These mineral scaffolds, resulting from a treatment to eliminate any trace of organic material, promote colonization of bone tissue via osteoconduction. They are slowly replaced by newly formed bone; both the quality and the quantity of lamellar bone is well documented and, at the moment, they are considered a first-choice material in bony defect repair in implantology, with the exception of class V and VI atrophies (Cawood and Howell¹), where the use of autogenous bone, alone or in association with xenogenic materials, is mandatory to rebuild the bony architecture prior to implant placement.

Biomaterials currently used in osseointegration

Anorganic bovine bone

This is an osteoconductive and slow-resorbing material composed of an anorganic mineral matrix deprived of the organic scaffold in order to leave intercrystalline microtunnels and microcapillaries between the bovine apatite crystals. The high osteoconductivity is due to the natural microstructure of the material, which demonstrates a large inner surface area and a system of intracrystalline spaces and microtunnels available for ingrowth of blood vessels and osteoblast migration. Long-term stability has been proved by many clinical studies. There must be no direct contact of the material with the implant surface for good implant osseointegration. The only early contact is between the clot and the matrix particles, and the angiogenesis and osteoblasts deposition occur from there. Integration is due to replacement of the bone substitute with newly formed bone. Histomorphometric analysis demonstrated that anorganic bovine bone increases the mineral portion in regenerated areas as compared to host bone areas.⁸⁻¹² Some of the material remains in the bone tissue and is slowly embedded in lamellar bone, resulting in denser bone, and this could explain the high survival rate of implants placed in areas augmented with it.

Calcium phosphate

Depending on the Ca/P ratio, the presence of water and impurities, this material crystallizes into two different shapes:

- calcium hydroxyphosphate or hydroxyapatite (HA);
- beta calciumtriphosphate (beta TCP).

Synthetic HA has the same chemical composition as human HA, but a slightly different structure. Its rate of metabolism by the human body depends on its structure, chemical composition, and interface surface area.

Beta TCP is also resorbable and is slowly converted to HA inside the human body; it supports early bone apposition (woven bone), although beta TCP's degradation products may provoke an inflammatory response that impairs and reverses bone apposition in the defect site. Histologic evaluations showed a solid host-bone connection at 9 months,¹³ but newly formed bone is confined to the periphery of the graft, the center being partially filled with connective tissue. This material can only be said to be basically resorbable, and no conversion process to trabecular, functional spongiosa occurs, since remodeling cannot take place. A recent report on sinus elevation showed

no difference between a test site treated with beta TCP and a control site treated with autogenous bone in terms of quantity and rate of ossification in a significant sample of patients.¹⁴⁻¹⁶

Calcium sulfate

This material has been used as a synthetic grafting material. Once the sulfate is embedded with water, an exothermic reaction results in crystalization and hardening of the granules. The host bone forms in concentric layers around the resorbing sulfate, which is different to the situation with other ceramics. Dense calcium sulfate does not seem to stimulate early bone apposition, but bone repair is more advanced at 12 weeks as compared with those treated with beta TCP, despite beta TCP's support for direct bone apposition at 1 week. Calcium sulfate appears to provide a more stable osteoconductive scaffold^{16,17} and seems to be a good material in sinus elevation.¹⁸ The osteoconductivity of calcium sulfate is documented, but the clinical experience remains limited.¹⁹

Calcium carbonate

This material is derived from calcified coral polyp skeletons with an aragonite crystal structure and mineral trace elements. Histologic examinations showed absence of direct bony ingrowth of the carbonate in the bone, while connective tissue appeared to encapsulate the implant, isolating it from the autogenous bone and preventing osteoconduction. Bone remodeling looks incomplete due to an insufficient amount of newly formed bone.²⁰⁻²²

Bioactive glass

This is a resorbable amorphous material composed of silicon dioxide, calcium oxide, and sodium oxide. The osteoconductive property is documented,^{23,24} but the most reliable clinical studies in sinus elevation were carried out using a mix of bioactive glass and autogenous bone in single-arm studies or comparing a mix with a control test represented by autogenous bone alone. Studies evaluating bone repair using bioglass alone are necessary to verify the properties of such a material.

Demineralized freeze-dried bone allograft

This material, from human donor bone, has been extensively used in the treatment of periodontal and periapical osseous defects. The material provides a source of type I collagen, which is the only organic component of bone. The processed bone results in lyophilized particles demineralized with hydrochlo-

ric acid. The particles are then recovered by centrifugation, frozen and freeze-dried again. Many reports confirm its ability to induce new bone formation²⁵ thanks to the exposure of BMP, whose inductive properties are well known. Despite this property, DFDBA's osteoinductive action has never been demonstrated and it seems that the regenerated bone is insufficient either in quality or in quantity to allow predictable implant placement, particularly following sinus elevation procedures.^{26,27} Other clinical studies confirm the reliability of DFDBA in sinus elevations, but always in conjunction with other materials.²⁸ Similar results are reported relating to the use of DFDBA in association with expanded polytetrafluoroethylene (e-PTFE) membranes.²⁹

Surgical techniques

The choice of procedure for reconstructing the posterior areas of the maxilla depends both on the depth and the extent of the defect. Starting from the postextraction defects up to the most severe atrophies, the classification according to Cawood and Howell¹ clarifies, in a simple way, what kind of surgical technique is the most suitable for each specific bony defect. In accordance with that classification, the defects can be listed as follows:

- postextraction sites;
- horizontal defects (including dehiscences and fenestrations around implants);
- vertical defects;
- combined (vertical and horizontal defects);
- sinus elevation.

Postextraction sites

An alveolar bone loss of 23% in the first 6 months after tooth extraction and of 11% during the following 5 years was demonstrated by Carlsson.³⁰ Alveolar bone loss not only reduces the amount of bone available for adequate support of the prosthetic load, but can also adversely affect the implant position, the peri-implant hard and soft tissue anatomy, and, consequently, the final esthetic and functional outcome. The immediate insertion of an implant in a postextraction site would therefore preserve a greater amount of alveolar bone and also reduce the treatment time. Whenever an immediate implant placement cannot be carried out due to the impossibility of obtaining primary stability for the fixture, physiological resorption due to the remodeling processes must be avoided. This goal can be easily achieved by filling the alveolus with bone substitutes and a free gingival graft, and implant placement surgery can be carried out about 6 months later.³¹

Where there is an infection in the extraction area, immediate implant insertion should be avoided and the surgery postponed until 40–60 days after the extraction.

Immediate technique

When the gap between implant and alveolus is less than 1 mm, tissue regeneration is entrusted to the clot. For larger gaps, bone substitutes can be used to fill the defect and the area is covered with a collagen membrane and a free gingival graft, which improves the quantity and the quality of the soft tissues around the implant at the time of connection of the healing abutment (Fig. 26.1). The soft tissue graft is obviously useless in cases of immediate temporary crown placement.

Delayed technique

In this situation, 6–8 weeks are needed to rebuild the gingival tissue after extraction and implant placement is performed by means of a standard procedure.

Horizontal defects

These defects occur where there is adequate height but insufficient width of the ridge. They include implant dehiscences and fenestrations and can be

treated with GBR procedures associated with autogenous bone chips and bone substitutes as well as ridge expansion techniques (at implant placement time) or autogenous bone blocks (prior to implant placement).

Dehiscences and fenestrations

Dehiscences are exposures of the implant at the level of its head, occurring when the thickness of the ridge is insufficient in the most coronal area. Fenestrations are exposures of the middle third or the apical portion of the implant with or without involvement of the implant head.

A bone regeneration technique using autogenous chips, bone substitutes, and resorbable or non-resorbable membranes is a possible treatment. Most dehiscences and fenestrations can easily be treated with a resorbable membrane acting as a stabilizer of the underlying material (granules or chips). When the exposed surface of the implant exceeds 1 mm outside the bone envelope and a large volume of bone has to be regenerated, non-resorbable e-PTFE membranes are indicated. In both cases, membranes have to be stabilized with pins or mini-screws and periosteal releasing incisions of the buccal flap are mandatory to avoid tension at suturing. Vertical mattress and single sutures are required in all the techniques.

Fig. 26.1 Case 1. (a) Periapical radiographs: first premolar affected by external root resorption can be seen. (b) Tooth extraction: the socket can be seen. (c) A 4.3mm implant placed immediately after tooth extraction. Anorganic bovine bone is used to fill the gap between implant surface and bone structure. (d) Final intraoral view after gold ceramic crown placement. (e) Periapical radiograph: final control.

Autogenous intraoral or extraoral blocks

Harvesting bone blocks from inside the mouth (chin, mandibular body or ramus) is indicated in the correction of a class IV atrophic ridge, particularly in the case of an extended narrow ridge. When a larger amount of bone is necessary (such as a resorbed maxillary ridge in edentulous patients) blocks can be harvested from the hip or the calvaria. In all these situations, attention must be paid to the block's resorption during the 4 months' healing. An average resorption of 20–30% can be observed^{32,33} at implant placement time, in blocks harvested from the chin or the hip, due to their cancellous component; and 15% resorption occurs in blocks harvested from the mandibular body and the ramus, which are basically made of cortical bone. An original technique to reduce the resorption of autogenous blocks was presented in 2005,³⁴ involving a layer of anorganic bovine bone placed on the top of the block and covered by a collagen membrane. Using this procedure it is possible to maintain the original size of the block; it can be successfully used for either intraoral or extraoral grafts (Figs 26.2, 26.3).³⁵

Vertical defects

If the bone height is insufficient to guarantee long-term implant stability or the prosthetic rehabilitation would result in too long crowns, vertical ridge augmentation is mandatory. Vertical augmentation can be achieved by means of corticocancellous blocks harvested from the chin or the ramus or, alternatively, with cancellous bone chips, bone substitutes, and a titanium-reinforced e-PTFE membrane.^{36,37}

Vertical GBR with membrane

This procedure is very predictable, but it has to be carried out strictly according to the surgical protocol, in order to limit the risks of the membrane exposure.

The most common flap design comprises a full-thickness mid-crestal incision within the keratinized mucosa of the edentulous ridge, extended mesially and distally to at least one adjacent tooth. Vertical releasing cuts are performed at the mesial and distal line angles of the incision. A proper preparation of the recipient site is crucial for new bone formation. The buccal and palatal flaps are reflected and gently managed to avoid any perforation of the flap. Stainless steel mini-screws are used as "tent poles" to prevent collapse of the membrane and to predetermine either the width or the height of the future alveolar ridge. The mini-screws are placed and left to protrude out from the bone level to the expected height. The cortical plate is then drilled with a round bur to expose the cancellous bone and to provoke some bleeding. The titanium structure of the e-PTFE membrane is bent with pliers to adapt it to the ridge anatomy and it is trimmed with scissors to extend at least 4–5 mm

beyond the margins of the defect. Once placed over the surgical recipient site, the membrane is secured to the lingual/palatal aspect of the bone crest with fixation mini-screws or pins. The cancellous autogenous chips mixed with the bone substitute are placed to reconstruct the defect and the buccal portion of the membrane is adapted to the vestibular bone plate, and also secured with screws or pins. A releasing horizontal incision of the periosteum is now performed to give elasticity to the flap and obtain tension-free adaptation at closure. The two margins of the flap can be considered sufficiently released when they overlap by at least 7–10 mm. Closure is done with horizontal mattress sutures first and with interrupted sutures later. The membrane is usually removed 6 months after surgery, at implant placement time. See Fig. 26.4.

Sinus elevation

When atrophy of the posterior maxilla reduces the amount of bone suitable for implant placement and a bone augmentation procedure is required, first of all one needs to evaluate if the sinus really has migrated from apical to coronal towards the margin of the alveolar ridge or if the sinus is in its previous position and the vertical height loss is due to vertical resorption. In the first case, a sinus elevation procedure is indicated, while in the second situation vertical ridge augmentation should be performed without any sinus involvement.

Once the necessity of performing a sinus elevation has been decided upon, the second step is the choice between a one- or a two-stage procedure. According to the recent literature,³⁸ a residual alveolar ridge of 4 mm is the absolute minimum height for bone augmentation and simultaneous implant placement and a two-stage technique must be done where there is a residual height of 0–4 mm.

The surgical procedure is the well known Boyne and James technique³⁹ and autogenous bone or bone substitutes have been used for a long time to fill up the subantral cavity. At present, long-term prospective and retrospective studies confirm that bone substitutes are able to regenerate new bone without harvesting autogenous bone and that the implant survival rate in augmented sinuses with biomaterials is significantly higher than that obtained using autogenous bone chips.^{40–42} In Cawood and Howell¹ class VI defects only autogenous bone is recommended, since the severe atrophy needs all the power of an osteoproliferative material.⁴³ This means that at least 80% of sinus elevation procedures can be done by using biomaterials alone.

What kind of bone substitute should be chosen to get the best result? All the bone substitutes currently used in the sinus elevation procedures, either xenogenic or alloplasts, offer osteoconductive properties only. The decision should be taken after considering the human hydroxyapatite structure: the more a

granule of a biomaterial is similar to a human hydroxyapatite crystal, the more it is possible to get an osteoconductive effect. Another parameter to be taken into consideration is the biomaterial's resorption time. A material which is resorbed too quickly does not allow the osteoblasts and the new vessels to promote formation of woven bone. A material which is resorbed too slowly, by delaying its total substitution with newly formed bone, inhibits bone-implant contact which is essential for osseointegration. A resorption time of 6–10 months can be considered reasonably ideal. In the author's experience, anorganic bovine bone has given excellent results in over 15 years of sinus elevation surgeries, giving a new bone quality close to a class 2 native bone⁴⁴ and a very

good osteoconductive property, as verified from many histomorphometric studies.^{45–47} Nevertheless, the author has been using other bone substitutes, such as beta TCP, calcium sulfate, and DFDBA, whose clinical efficacy has been demonstrated in some studies, although with a lower predictability in terms of bone quality and implant survival rate.

When the height of the residual ridge is 6–7 mm, the surgeon can decide whether to use short implants or elevate the sinus floor 2–3 mm with the Summer's osteotome technique. The procedure, wrongly named "minor sinus elevation" is a blind procedure and should be considered with care. In order to elevate the sinus membrane with this procedure, any of the biomaterials can be equally used, since the primary

stability of the implant is guaranteed by the residual ridge.⁴⁸ See Figs 26.5, 26.6.

Biomaterials in major advanced osseointegration

As described with regard to the intraoral autogenous blocks, biomaterials can be successfully used to reduce the iliac crest blocks with the same coverage technique. The author's clinical experience using anorganic bovine bone as an agent to limit autogenous

bone resorption allows him to conclude that the coverage technique can be routinely used with absolute predictability even in cases of a whole maxillary or mandibular reconstruction.³⁵

Another way to use biomaterials in major reconstructions is the combination of bone substitutes and cancellous iliac bone as described by Boyne in his presentation of the titanium mesh technique for the upper jaw.⁴⁹ The cancellous–anorganic bovine bone mix in a 1:1 ratio is used to fill up a titanium mesh model made in an individual tray (Fig. 26.7). The titanium mesh is secured to the palatal vault and kept in

Fig. 26.6 Case 6. (a) Preoperative panoramic radiograph: before teeth extraction in the left upper jaw, 2 months before sinus lift procedure. (b) Sinus lift procedure and implant placement. Hydroxyapatite granules used to fill the subantral cavity can be seen. (c) Postoperative panoramic radiograph. (d) 1 year follow-up panoramic radiograph: no sign of graft resorption or peri-implant bone loss can be seen.

Fig. 26.7 Case 7. (a) Preoperative computed tomography (CT) scan: severe horizontal bone atrophy can be seen. (b) Intraoral view: extreme bone resorption can be appreciated. Bilateral sinus lift procedure performed before bone augmentation by means of titanium mesh. (c) Titanium mesh filled with a mixture of anorganic bovine bone and autogenous bone chips harvested from the hip. (d, e, f) Titanium mesh fixed to the palate by means of two cortical screws. (g) Postoperative panoramic radiograph. (h) Soft tissues healing after titanium mesh removal and fornix deepening procedures. (l) 5 year panoramic radiograph follow-up.

place for 5 months. The use of such a bone substitute helps to maintain the original volume of the graft during remodeling and contraction of the autogenous part, and so helps to determine increased firmness of the regenerated bone at implant placement time.⁴⁹⁻⁵¹

Developments: growth factors and BMP

A new field in implantology is developing with the aim of finding new ways to improve the osteoconductivity of bone substitutes and to study new molecules able to dictate cellular differentiation and improve bone regeneration. The so-called growth factors are biological mediators which promote cell proliferation. Some of these growth factors have been proved to have the ability to contribute to bone regeneration, PDGF (platelet-derived growth factor) in particular. PDGF is secreted by different cell types, such as platelets, osteoblasts, and activated macrophages,⁵² and is able to stimulate chemotaxis, cell proliferation, and protein synthesis.⁵³ Some clinical studies are currently running on the use of different carriers for PDGF in GBR. PDGF is also one of the factors contained in platelet-rich plasma (PRP), a platelet concentrate produced by plasmaphoresis using centrifugation; this is mixed with autogenous bone chips or bone substitutes in order to add osteoinductive properties to the graft. Different growth factors can be recognized within PRP: transforming growth factor (TGF- β), insulin-like growth factor (IGF), fibroblast growth factors (FGF), and others. The initial technique was presented by Marx, starting from a large blood sample.⁵⁴ Variations were applied in order to simplify the original procedure.⁵⁵ After the first promising results using PRP in different ways, studies confirmed that the activity of PRP is significant only in the presence of autogenous bone, while disappointing results are reported in cases where PRP is used in association with bone substitutes. In fact, no significant differences in terms of vital bone production in sinus elevation with anorganic bovine bone or DFDBA are reported.⁵⁶⁻⁶⁰

The real future in bone regeneration seems to be in connection with the BMPs, currently obtained by synthesis using recombinant DNA. BMPs are part of the TGF- β family but, different to the other growth factors, they have an osteoinductive property. They are exogenic cytokines and act on adult mesenchymal stem cells, which are responsible for all the bone healing processes; their effect, however, depends upon the vector used to deliver the fluid BMP into the site to be regenerated. Different carriers have been studied, such as collagen, polylactic acid granules, anorganic bovine bone, corals, etc., and the ability of BMP-2 and BMP-7 has been investigated.⁶¹⁻⁶³ In the first studies in humans by Boyne,⁶⁴ rhBMP-2 was used in sinus elevation, showing trabecular bone formation after 16 weeks and similar results in terms of

bone regeneration came from Cochran, Howell, and Jung.⁶⁵⁻⁶⁷ Recent data from Boyne⁶⁸ confirm the reliability of rhBMP-2 in sinus elevation when carried by a resorbable collagen sponge. Further data are necessary to confirm the preliminary results, but in the near future the use of BMPs will considerably change the approach and the treatment of maxillary atrophy.

Chapter 27

The Zygoma Implant for the Totally Atrophied Maxilla

Chantal Malevez

The chapter describes the anatomic characteristics of the zygoma bone. Zygoma implants are described and possible indications for use in implant rehabilitation listed. The surgical technique is described in detail according to a standard protocol. Flapless, guided surgery as well as use of four zygoma implants are other methods included in the chapter. Immediate or delayed loading of the implants is another point of discussion. Zygoma implants have demonstrated a high success rate in the severely atrophied maxilla, however complications that may happen are discussed at the end of the chapter.

Introduction

The concept of osseointegration provides viable treatment options to patients with partial or complete loss of teeth, and many patients benefit today from predictable oral rehabilitation by means of implants.¹

Patients' motivations for seeking implant-based therapy mostly involve issues of chewing, comfort, self-confidence, and appearance. Edentulousness has always been considered to be a normal effect of ageing, however most people avoid talking about this handicap or explaining how much it affects their professional as well as social life. People suffering total edentulousness restrict their social contact, losing self-confidence and developing fear of discomfort with their removable prosthesis in public, restrict-

ing the choice of the food they are able to chew, and also limiting their speech.

People want to live long and well, free from infirmity, impairment, disability, and handicap; the concept of quality of life has become fundamental in recent years. There is no universally accepted definition for quality of life. Oral health-related quality of life reflects four aspects of oral health: (1) speech and mastication; (2) pain and discomfort; (3) appearance and self-esteem; (4) intimacy, communication, and social relationships. These are of relevance even in maxillectomy cases.² Undoubtedly increasing life expectancy has heightened people's expectations. However edentulousness can occur early in life (20 years). At this age, the removable prosthesis is well tolerated and stability is obtained thanks to the volume of the maxilla and to the presence of retention sites.

It is very common to see patients of less than 60 years of age with a dramatic resorption of the maxilla and sometimes no more than 2 mm height under the nose and the maxillary sinuses. In terms of prosthetic reconstruction, fixed or removable, this kind of situation is no different from edentulousness at the age of 70 or 80: the handicap remains the same (no stability, sourness, difficulty of chewing, ageing face) but it appears earlier in life. Ageing depends on inherited factors, environmental factors, and personally controlled factors.

In many studies, the mean age of the patients treated by means of zygoma implants is 58 years^{3,4} confirming the distress of these patients. Most of the time, at this age, patients are still involved in professional life as well as in a social one. Their well-being is fundamental but, despite the fact that they are handicapped, they have no time to spend in lengthy treatments.

Treatment of the atrophic upper jaw depends on the severity of the atrophy and also on the patient's systemic condition, age and health, and on other functional parameters like interarch ratio, oral hygiene, and phonetic aspects. Regarding esthetic requirements, patients have to understand the advantages

and limitations of different types of prosthetic rehabilitation in terms of comfort, compensation for the lack of volume, and adequate lip support. Fixed rehabilitation by means of bridges seems to be the treatment of choice in young and middle-aged patients. Some clinicians consider that removable prostheses are adequate for older patients. However, ageing, with decline of muscular coordination, force, modification of eating habits, and compromised oral hygiene, increases the need for a fixed denture situation. There is no objective reason to provide older patients with removable dentures.

When the clinician takes time to try to understand the wishes of the patient, he or she will discover that younger people are more concerned with esthetics than older patients, but that correct chewing and easy cleaning are mandatory for older patients. However old patients do want to be good looking and avoid an ageing face due to the absence of lip support. They ask for esthetic results too, and they agree that artificial teeth provide them this lip support.

It is well known that providing the patient with a removable prosthesis is not satisfactory even if some studies try to prove that there is no significant difference between a removable prosthesis and a prosthesis fixed on implants. Providing standard implants in cases of relatively minimal bone resorption, which allow the construction of fixed bridges, considerably improves quality of life and patients recover self-esteem and confidence. They regularly say, "My life has changed." They have found a solution to all their complaints.

For many years, it was recommended to wait 6 months before loading the implants to obtain osseointegration; today the development of new surfaces, new implant designs, and modified surgical protocols has improved the quality or the primary stability⁵ leading to a final goal: immediate loading of the implants, rebuilding the occlusion, function, and esthetic lip support in one stage. This new approach completely changes the length and the philosophy of treatment.

For a normal rehabilitation of the totally edentulous upper jaw, standard implants are usually placed in the anterior part of the maxilla allowing the placement of four to six implants supporting a fixed bridge of 12–14 teeth.⁶ Bone loss is compensated for by the prosthesis with the use of longer teeth or a flange of pink acrylic simulating papillae and soft tissue. Tilted implants⁷ placed in the anterior maxilla can also be indicated in cases of deep maxillary sinus extensions, implants being placed tangential to the sinus borders. They are as long as possible, the implant entry point being at the level of the second premolar and the upper anchorage in the canine pillar.

Unfortunately loss of teeth is followed by loss of bone and lack of bone volume in the anterior part as well as in the posterior section of the maxilla. This situation can be a real problem for the rehabilitation of the patients either by means of removable prosthe-

sis or by means of implants. The amount of bone remaining under the sinus as well as under the nasal fossa can be as little as 1 mm. Patients who are completely edentulous at the age of 20 have to face this atrophy from the age of 40, so, consequently, this situation is very common in patients of 56–57 years of age.

Patients with a mobile removable denture develop anxiety and fear of losing their prosthesis at work as well as while socializing, during intimacy and contact with friends. In these cases with severe bone resorption, implant placement is impossible without additional techniques.

Some 20 years ago, the first solutions were bone volume augmentation with the hope of restoring the maxilla to how it was in the past.^{8,9} Many techniques have been proposed with different success rates: sinus grafts,^{10–12} onlay-inlay bone grafting, osteotomies. They all have the aim of augmenting the bone volume with different kinds of materials: autologous bone grafts, bovine bone grafts or artificial materials.^{9,13} Despite the fact that these treatments are valuable and well documented, they are lengthy, sometimes unpredictable, and cause discomfort for the patients depending on which kind of grafted material is used.

The zygoma implant (zygoma implant, zygomaticus fixture) was introduced by PI Brånemark in the early 1980s¹⁴ for severely atrophied maxillae without discontinuity, after his successful experience in the rehabilitation of defects of the upper jaw,¹⁵ where he imagined using the zygoma as an anchorage for oral implants.

Since 1997, the zygoma implant (the so-called zygomaticus fixture) has been developed throughout the world for totally edentulous patients; it was also later developed for partially edentulous cases. The zygoma implant was initially proposed as an alternative to sinus grafts, reducing morbidity, length of the treatment, discomfort, and improving quality of life of the patients. With time, survival rates appeared to be satisfactory.^{16–23} Moreover, as has been suggested for treatment in the lower jaw with the Brånemark Novum,²⁴ it is today possible to load standard implants^{25,26} and zygoma implants immediately, restoring chewing function, speech, and esthetics on the day of the surgery.^{27–29} The surgery is a safe procedure but it is necessary to have good knowledge of anatomy and to follow the guidelines proposed in the protocol.

The zygoma

The question: Can the zygoma be a satisfactory anchorage for oral implants?³⁰ The zygoma bone is attached to the frontal bone, the sphenoid, the temporal bone, and the maxilla, this last through the zygomatic apophysis. It looks like a pyramid with four faces and an inferior top (Fig. 27.1).

Fig. 27.1 View of the bulky form of the zygoma.

Features of the zygoma bone

Bone quality

In a study on the rabbit, Gosain showed the zygoma was a regular trabecular bone with high density.³¹ In a study on the human zygoma, Nkenke showed the zygoma had quite poor trabecular density but very strong cortical bone that could ensure primary stability of implants inserted in its cortex (Fig. 27.2).³²

Length and volume

In a study on 14 cadavers and clinical cases realized in February 2001, it was shown that the mean height of the zygoma is 14mm and the anterior-posterior width is 20.5mm.³³ Trabecular bone is found all along the total height of the zygoma bone and cortical bone is present at two levels in the lower part of the zygoma as well as in the upper part.³⁴ From the anatomic point of view, it can be concluded that the zygoma offers an anchorage that, according to Brånemark's definition, would probably provide osseointegration for a long period of time with long-term results.

Anchorage

The zygoma is a well known multidisciplinary anchorage:

1. In orthodontics: with the use of perizygomatic wire³⁵ placed around the zygomatic arch or mini-

- plates³⁶ screwed on the zygoma to obtain retraction of the incisors by progressive traction.
2. In maxillofacial prosthetics: the zygoma is used as an anchorage for extraoral transcutaneous implants supporting orbital prostheses.¹
3. In maxillofacial surgery: miniplates are used for repair of fractures and the zygoma provides a solid anchorage for the miniplates.³⁷
4. In research: in an experimental study on the monkey, the resistance of titanium implants inserted in the zygoma and submitted to heavy traction for mobilizing the maxillofacial complex after a Le Fort III osteotomy was shown.³⁸
5. In reconstructive surgery: PI Brånemark used the zygoma bone as an anchorage for maxillofacial prosthesis after tumor resection.³⁹

From this multidisciplinary experience, it is concluded that the zygoma bone resists different types of forces applied to it.

The zygoma implant

Extreme atrophy of the posterior maxilla makes it impossible to insert implants without augmenting the bone volume except if an anchorage can be found at a level other than the maxilla, i.e. the zygoma.^{22,34,40} Alveolar extension of the maxillary sinuses also reduces the length of the arch where regular standard implants could be inserted. With bone graft failures, bone volume is also reduced diminishing the possibility of using regular standard implants. Another issue is the rehabilitation of maxillectomized patients after tumor resection.

As seen previously, the zygoma offers a strong and stable anchorage^{34,41} at a level other than the maxilla. Two zygoma implants can be used in conjunction with two to four anterior standard implants when sufficient bone remains in the anterior part of the maxilla. In these cases, minimal bone height of the premaxilla should be 10mm and minimal width

Fig. 27.2 Thick cortical bone and spongy trabecular bone.

4 mm. The zygoma implant has its emergence point at the level of the second premolar/first molar. Depending on the anatomy of the patient, the emergence point will be crestal or slightly palatal or slightly buccal.⁴² The zygoma implant has to be connected to other implants to support the load of the masticatory forces.⁵

Immediate loading avoids the need to wait for a long period before allowing regular masticatory function by means of a fixed prosthesis screwed on to the implants. Immediate rigid splinting of the tilted implants distributes the axial and lateral loads and stabilizes the whole system.

In extreme resorption of the maxilla (1 mm height) the majority of authors usually recommend large autogenous bone grafts. These reconstructions can offer a solution, but the use of four zygoma implants would seem to be the treatment of choice.²⁶ As described before, the volume of the zygoma is sufficient for the insertion of two zygoma implants with great stability, providing good support to a fixed prosthesis immediately screwed on to them.

Description

The zygoma implant is a self-tapping angulated implant (Nobel Biocare AB) made of cp titanium with two surfaces, one machined and one Tiunite,⁴³ and presenting two diameters on the same implant, 3.9 mm at the top and 4.6 mm at the maxillary level. It exists in different lengths: 30, 35, 40, 42.5, 45, 47.5, 50, and 52.5 mm. The 3.9 mm part corresponds to the mean volume of the zygoma and 4.6 mm to the width of the maxilla at the level of the second premolar/first molar.

The interesting 45° angulation corresponds to the angulation of the zygoma bone with the maxilla.

Fig. 27.3 The Tiunite zygoma implant and the machined implant with their fixture mount.

Fig. 27.4 The angulated edge for the maxillary level.

Some authors propose zygoma implants with 55° angulation.⁴⁴ In cases of extreme atrophy, this angulation can be corrected by additional angulated abutments (17° and 30°). The roughness of the Tiunite surface augments the mechanical interlocking at the level of the zygoma, allowing immediate loading and immediate function (Figs 27.3, 27.4).

Indications and aims

The zygoma implant is indicated in:

- situations where the anterior volume of the maxilla is still sufficient for the placement of two to four standard implants but where the posterior maxillary crest is too atrophied and would need bone grafting;
- situations where the atrophy of the maxilla is extreme, but the zygomas allow the insertion of four zygoma implants.^{26,45}

The aims of the zygoma implant are:

- to ensure a posterior stable anchorage in difficult conditions: type IV bone and heavy atrophy (more than 7 mm);
- to avoid heavy bone grafting;
- to offer an alternative to sinus grafts;
- to offer fixed bridges to patients handicapped by mobile removable prostheses;
- to rehabilitate patients who have undergone resections of the maxillae.

Radiological examination

In the dental field, different kinds of imaging techniques are available: orthopantomogram, profile radiographs, scanora, computed tomography (CT) scan, cone-beam CT, including software allowing virtual planning. Scanora, CT scan, and, more recently, cone-beam CT are the ideal radiological approaches for the preplanning of the surgery. These imaging techniques enable one to:

- appreciate the sinus health and the possibility of ventilation by investigating the whole maxillary sinus cavity – sinus pathology like chronic sinusitis, papillomas, and aspergillosis can be detected;
- determine the topography of the anterior wall of the posterior temporal fossa (posterior wall of the sinus and the zygoma);
- estimate the volume of the maxillary bone;
- estimate the concavity of the anterior sinus wall.

Dedicated software^{33,46} also provides the possibility of performing virtual insertion of the zygoma implant before the surgery and planning surgical guides allowing flapless surgery, immediate loading, and immediate function (Fig. 27.5).

Fig. 27.5 Occlusal view of the zygoma with virtual insertion of the zygoma implant and of the other standard implants. The yellow color shows the security zone around the implant.

Surgery

Since 1997, when a protocol was first established for the insertion of zygoma implants, some modifications have been proposed by different clinicians. Despite the fact that the anatomy of the zygoma limits the orientation of the zygoma implants, the curve of the anterior wall of the sinus has also been considered to be a limiting factor. The more concave the sinus wall is, the more likely it is that the implant will have a palatal emergence point, that could jeopardize the

Fig. 27.6 After the flap is raised, opening of a small window.

prosthetic rehabilitation, encountering high cantilevered bridges. For these reasons, some authors proposed an extrasinusal insertion of the implants and a buccal position at the level of the maxilla.¹⁹ Mouth opening is also a factor limiting the possibilities of the zygoma implant insertion, because of the length of the drills and of the zygoma implants.

Conventionally following the classic protocol, the placement of zygoma implants can be performed as a day case or chairside under local or total anesthesia. The incision is sulcular (Le Fort I incision) or more often crestal or slightly palatal, with elevation of a full-thickness flap. The advantage of doing a palatal incision is to keep as much attached soft tissue as possible for covering the head of the implant after surgery.^{18,47} The flap is raised up to the zygoma, observing the suborbital nerve, the rim of the orbit, and the angle made by the zygomatic arch together with the zygoma and the zygomatic apophysis of the maxilla.^{17,46} A small window is opened in the anterior sinus wall at the level of the zygoma (Fig. 27.6).

This small window close to the level of the zygoma gives the surgeon the opportunity of a direct view of the whole zygoma and allows him/her to choose the orientation of the drilling procedure and of the insertion of the implant. A first round bur is then used for entering the maxilla and the zygoma and is followed by a sequence of three drills that will provide the bed of the zygoma implant (Fig. 27.7). The implant is then inserted up to the top of the zygoma with a low speed motor and stabilized with a special screwdriver ensuring the position of the implant perpendicular to the occlusal plane for prosthetic purposes (Fig. 27.8). Other standard implants (two to four) are then inserted in the anterior region (Fig. 27.9).

Where four zygoma implants are to be inserted, the anterior ones are positioned first. For this procedure, the window is a horizontal one that allows the

(a)

(b)

Fig. 27.8 Insertion of the zygoma implant. The head of the implant is seen at the top of the zygoma and the implant is seen through the window.

Fig. 27.9 Placement of four additional standard implants.

surgeon to have a view of the insertion of both implants (Fig. 27.10). The anterior one is positioned first after having detected the suborbital nerve. Its maxillary emergence point is at the level of the lateral incisor. The second implant, with its emergence point at the second premolar/first molar, is then inserted (Figs 27.11–27.13). The distance between both implants at the zygoma level should be at least 1 cm, for providing sufficient bone support and osseointegration.

Modifications of the surgical protocol have been proposed by different authors: sinus slot technique with a vertical window along the maxillary zygomatic apophysis,⁴⁸ vertical window pushing back bone and sinus membrane before drilling and insertion of the zygomatic implant,²⁸ with a technique comparable to the sinus graft technique, soft tissue punch at the level of the palatal mucosa combined with a Le Fort I incision,⁴² guided surgery for drilling and visual control of the insertion of the implant.²⁸

Insertion of the zygoma implant will depend on the anatomy of the anterior wall of the sinus and the

Fig. 27.10 Window where four zygoma implants are to be placed. Case realized in collaboration with R. Haas and G. Mailath-Pokorny.

Fig. 27.11 Simulation and preplanning.

bulky zygoma bone. Where the concavity of the sinus wall is deep, the zygoma implant inserted totally through the sinus would have a palatal emergence point. To avoid the implant being too palatal, it is possible to insert the implant parallel and in close contact with the sinus wall. In this situation, the implant remains external to the sinus membrane, and implants will only be anchored in the zygoma, with a close contact with the maxillary crest for obtaining a crestal position of the implant.⁴² Osseointegration will only be obtained at the level of the zygoma. From a biomechanical point of view, it is well known that masticatory forces applied to the prosthesis screwed on the implants are transmitted to the bony anchorage at the level of the zygoma. That means that osseointegration is not required at the level of the atrophied maxilla. With this insertion protocol, the sinus membrane is not damaged, and the zygoma implant remains totally outside the sinus. A more crestal position of the implants is also favorable for prosthetic reconstruction.

Flapless guided surgery (Nobel Biocare AB) is also being developed to minimize surgical degloving of the soft tissue and to improve the postoperative condition of the patient, with less swelling, less pain, no sutures, and the possibility of immediate loading.

Complications

Complications are few. Some authors⁴⁹ seem to have found deep pathological pockets around the neck of

Fig. 27.12 Case of four zygoma implants and extreme atrophy of the maxilla. Preplanning and surgery. (a) Placement of the first left implant. (b) Placement of the second left implant. (c) View of the four implants.

Fig. 27.13 Placement of a provisional prosthesis screwed on the four implants the same day. Case realized in collaboration with V. Choquet and T. Thomas.

the zygoma implants. These “pockets” are due to the fact that the zygoma implant emerges slightly palatal at a level where the healthy soft tissue containing fat cells can be 5–6 mm thick. Controlled hygiene avoids inflammation at this level and keratinized epithelium ensures a seal around the implants.

Most of the time, zygoma implants penetrate the sinus. This results in two risks: the first is the opening of the floor of the sinus so that, at the time of the surgery, it communicates with the mouth, and the opening of the zygoma at the top of the sinus. The second risk is the insertion of a foreign body⁵⁰ that could result in inflammatory reactions. Some authors have described 2–4% sinus inflammatory reactions or more.^{3,22,51}

Symptoms of sinusitis are swelling of the midface and suppuration from the nose. Microbiological tests and endoscopy can confirm the diagnosis. For resolution of the inflammation, control of the infection with reduction of swelling is necessary to correct ventilation and sinuses drainage.⁵² Antibiosis, corticosteroids, and local treatment can be proposed initially,⁵² before considering surgical treatment like meatotomies.

One hypothesis of the cause of sinusitis is the fact that the zygoma implants generate chronic inflammation of the sinus that diminishes sinus drainage and increases the amount of bacteria.

Another hypothesis is the creation of a communication between sinus and mouth due to the possible flexibility of the zygoma implant and a weak point at the maxillary bony level. Bacteria from the mouth could enter the sinus by this route. In the standard machined zygoma implants, there is a perforation of the head of the implant which houses the abutment screw, and this could facilitate the migration of bacteria.

Most of the studies show a maximum of 5% sinusitis. One study on a small number of patients describes nine patients out of 16 who suffered from sinusitis, but in this study poor hygiene as well as inflammation of the emergence point of the implants were implicated.⁵¹ The percentage of infections is comparable to the percentage of infections in sinus graft procedures.⁵⁰ Nevertheless, endoscopies also show very healthy sinuses.⁵³

Sinusitis involving osteitis of the zygoma has not been described. In cases where the integrated zygoma implant had to be eliminated because of recurrent sinusitis, it was impossible to remove it and it had to be cut at the level of the zygoma.

Since the development of this zygoma implant protocol in 1997, a number of modifications have been developed to improve the whole procedure:

- Better evaluation of the sinus health can be done with examination of the sinus meatus by CT scan before performing the surgery.
- With the new protocols of immediate loading, there is a single one-stage surgery without reopen-

ing of the soft tissue and an immediate stabilization of the whole rehabilitating system.

- The implant with the Tiunite surface does not have a perforation.
- Surgery can also be performed without entering the sinus, as described above.

All these modifications could lead to a diminished number of cases of sinusitis.

Other complications, e.g. acute sinusitis, hematoma, and transitional hypoesthesias of the suborbital nerve, have also been described. Fracture of implant is very uncommon and has so far been described by PI Brånemark in one case. Failure of osseointegration has been reported with results up to 9%.¹⁷ The palatal emergence site of the machined and Tiunite zygoma implant has been histologically analyzed, showing particularly healthy sites (Figs 27.14–27.16). The epithelium is a short, keratinized or parakeratinized epithelium very similar to the keratinized palatal epithelium. The lamina propria, i.e. the connective tissue underlying the oral mucosa, contains thick collagen

Fig. 27.14 Keratinized palatal epithelium.

Fig. 27.15 Thick palatal mucosa with: A, stratum germinativum; B, stratum spinosum; C, stratum granulosum; D, the stratum corneum.

bundles oriented towards the implant surface. No accumulation of bacteria or inflammatory response was visible at the interface.

Functional rehabilitation

As for the standard rehabilitation on standard implants, there are three possibilities available to the clinician:

- immediate loading and immediate function,^{5,24,25,29,54}
- early loading and immediate function with provisional prosthesis;^{25,29}
- two-stage surgery and delayed loading.

Immediate loading can be performed with a permanent prosthesis or a provisional one.^{27,28} To allow immediate loading, a complete removable prosthesis is prepared before the surgery in the usual way: occlusion, interarch relationship, vertical dimension, and masticatory conditions are evaluated. A surgical guide in clear acrylic can also be made to give more information for placing the implants in the ideal position.²⁶

The patient's immediate rehabilitation is performed exactly the same way as for standard implants. Immediately after the surgery, an impression is taken of the implants by means of transfers screwed on the abutments. The provisional prosthesis prepared before the surgery is attached to the transfers with an acrylic template, and a low-viscosity, silicon-type impression material is injected to copy as many details as possible. The prosthesis is then treated in the laboratory where it can be reinforced by carbon fibers or a metallic framework. The prosthesis is then inserted in the mouth of the patient and screwed on the implants within 24 hours and the occlusion is adjusted.

Fig. 27.17 (a) Final prosthesis made of gold and porcelain on two zygoma implants and three standard implants. (b) Smile of the patient showing good lip support.

Most of the time, fixed bridges are screwed on the implants to offer the patient comfort and precise application of occlusal forces. Some clinicians prefer to provide a bar system and removable prosthesis, considering this procedure more adequate for hygiene especially in old patients. However practitioners should remember that most of the studies show a mean age of 56–58 years, an age at which patients would probably prefer fixed bridges.

After 3 months, definitive prostheses are constructed with gold or titanium or zirconium frameworks and acrylic or ceramic teeth to ensure cosmetic results for the patient and compensate for the lack of volume due to the atrophy (Figs 27.17, 27.18).

Guided and minimally invasive surgery

Dedicated software provides the possibility of producing the provisional or definitive prosthesis before the surgery and screwing it on immediately, to allow immediate function.^{25,46} Virtual positioning of the implant is performed before the surgery and a surgical guide is fabricated following the NobelGuide procedure. At the time of the surgery, the guide is inserted in the mouth and fixed to the maxilla with several pins (Figs 27.19–27.22). Drilling is performed through the guide as well as the zygoma implant insertion by means of special hardware that places the zygoma implant in its exact position. The definitive prosthesis is screwed on the implants.

Fig. 27.18 Titanium framework on four zygoma implants.

The advantages of this technique are:

- Reduction of time for the surgery and the prosthetics. The patient encounters less swelling and pain that limits discomfort.
- Restoration of chewing function same day with a fixed prosthesis that gives the patient a feeling of security and self-esteem improving quality of life.
- Reduction of costs, limiting chairside treatment to a minimum.

This procedure is still in development, and will benefit from more scientific research for validating the surgical guide and the flapless procedure.

Conclusions

Zygoma implants have demonstrated a high survival rate in severely atrophied maxillae, with minimal complications. This alternative to sinus grafting and other kinds of bone volume augmentation shortens the surgical procedure, reduces costs, diminishes the length of the rehabilitation, and there is the possibility of immediate loading and function, improving quality of life for the patient.

Clinicians should be aware of the fact that edentulousness can start very early in life, affecting chewing function, speech, esthetics, well-being, and self-esteem.

Whatever the surgical approach is, crestal or paracrestal, slightly buccal or palatal, the point of

emergence of the zygoma implants is usually at the level of the second premolar/first molar. This position allows the use of cantilevered fixed bridges, up to the first or second molar, reconstructing a full arch for functional and esthetic purposes.

Where four zygoma implants are used, the anterior ones emerge at the level of the canine/lateral incisor

and the posterior ones at the level of the second premolar. The use of four zygoma implants increases the strength of the anchorage and offers a distribution of the masticatory load in the zygoma, a bony structure of excellent quality.

Strict hygiene is mandatory to avoid inflammation of the soft tissues around the emergence point of the

implants that could create possible fistulas. However, in cases where inflammation was observed, it never compromised the osseointegration of the zygoma implants.

More studies, especially on partial edentulousness, are needed to validate this procedure and give another alternative to patients. Development of new technologies like guided surgery should be validated to diminish the risks and possible complications of these protocols and establish guidelines for the clinicians. Modifications of surgical protocols as proposed by the author should diminish complications like sinusitis that jeopardize the treatment.

Zygoma implants have yet to find their place in the routine treatment of patients suffering from extreme atrophy of the maxilla that jeopardizes their professional and social life.

Chapter 28

The Role of Implants in Maxillofacial Reconstruction

Arun B. Sharma and John Beumer III

The chapter is a comprehensive overview of the role of implants in the reconstruction of major defects in the orofacial region. Malignant tumors, with their extensive resections, are frequently the cause of disfiguring facial defects. A variety of prosthetic techniques to treat such patients is presented.

Maxillary defects, 451
 Prosthetic treatment, 452
 Definitive soft palate prosthesis, 454
Tongue–mandible defects, 455
 Free bone grafts, 456
 Free vascularized flaps, 456
 Definitive prosthetic restoration, 457
 Implant-assisted overlay dentures, 457
Facial defects, 458
 Surgical reconstruction vs prosthetic restoration, 458
 Alterations at surgery to enhance the prosthetic prognosis, 459
 Prosthetic facial restorations, 459
Implants in irradiated tissues, 461
 Predictability of implants in irradiated bone, 462
 Irradiation of existing implants, 463

Treatment of oral and facial cancers can result in severe oral dysfunction and facial disfigurement but today it is possible to restore many patients to near normal form and function, enabling them to continue to have useful and productive lives. In the late 1980s several technical improvements were made – for example the development of osseointegrated dental implants and free vascularized flaps – but in recent times the most significant improvements have been the result of improved collaborations between medical and dental researchers and clinicians. In the leading cancer centers of the world, prosthodontists see and examine the patient prior to their cancer treatment and work with their colleagues in surgical oncology, reconstructive surgery or radiation oncology to minimize post-treatment morbidities and to develop plans to rehabilitate the patient. Presently with a proper multidisciplinary approach to patient care, almost all patients, treated with surgical resection and/or radia-

tion for oral or facial cancer can be very effectively rehabilitated, retaining their ability to speak, swallow, masticate and control their saliva, enabling them to interact socially with family, friends, and professional colleagues.

Head and neck cancer patients who require maxillofacial rehabilitation may be arbitrarily classified according to their post-treatment surgical defects and morbidity, which include maxillary, tongue–mandibular, and facial defects. This chapter will concentrate primarily on the role of implants in the restoration of defects secondary to surgical ablation of head and neck tumors.

Maxillary defects

Most tumors arising from the paranasal sinus, palatal epithelium, or minor salivary glands require either a partial or radical maxillectomy (Fig. 28.1a). Defects of the hard or soft palate produce a variety of problems: hypernasality makes speech unintelligible; mastication efficiency is compromised, particularly for the edentulous patient, because teeth and denture-bearing tissue surfaces are lost, and support, stability, and retention of the maxillary prosthesis are compromised; swallowing is awkward, since food and liquids may be forced up into the nasal cavity and out the nose; nasal and sinus secretions collect in the defect area; and facial disfigurement can result from lack of midface bony support.

Rehabilitation after resection of the hard or soft palate is best accomplished prosthetically. Customarily, a temporary prosthesis, known as an immediate surgical obturator, is placed at the time of surgery. During the healing period, this prosthesis is relined periodically with temporary denture liners to compensate for tissue changes secondary to organization and contracture of the tissues adjacent to the defect. When these tissues are well healed and dimensionally stable (usually 3–4 months after surgery), the definitive prosthesis is made. Inadequate retention, stability, and support are the main problems associated

with the use of an obturator prosthesis. The remaining teeth, therefore, become extremely valuable in providing support, retention, and stability for these restorations. If there are adequate numbers of teeth remaining after the resection to provide the support, stability, and retention for the obturator prosthesis, then surgical reconstruction should not be considered (Fig. 28.1).

Almost all defects of the hard palate are restored effectively with a prosthesis. Best results are achieved when the surgeon prepares the defect for the obturator prosthesis by skin grafting the defect, sparing the premaxilla when possible, removing unwanted turbinates enabling appropriate access to the defect, and making alveolar bone cuts in such a fashion as to maximize the effectiveness of abutment teeth adjacent to the defect.¹ When the patient is edentulous or the remaining teeth do not have a favorable prognosis, osseointegrated implants (Fig. 28.2) can be used to enhance support, stability, and retention of the obturator. The purpose of these prostheses is to restore the physical separation between the oral and nasal cavities, thereby restoring speech and swallowing to normal, and to provide support for the lip and cheek.

Prosthodontic treatment

It is essential that the prosthodontist examines and consults with the patient before surgery. The sequence of treatment should be explained to the patient, and

Fig. 28.1 (a) Large maxillectomy defect. (b) Maxillary obturator. (c) Prosthesis in position. Speech, mastication, and swallowing are restored to normal.

Fig. 28.2 Edentulous patient with partial palatectomy defect. Implants provide retention, stability, and support for obturator prosthesis. Note rests (arrows) on the bar and resilient attachments.

Fig. 28.3 Implants being inserted following maxillectomy.

diagnostic casts and appropriate radiographs should be obtained. With this information, the prosthodontist is ready to consult with the surgeon. In edentulous patients, the placement of osseointegrated implants into available maxillary sites should be considered for patients not scheduled for postoperative radiation. These implants can be used later to facilitate the retention and stability of, and support for, the future obturator prosthesis (Fig. 28.3).

Teeth greatly improve the retention and stability of the obturator prosthesis. In the absence of teeth, osseointegrated implants can provide similar retention and stability for the obturator. Speech, swallowing, mastication, and facial contour can be restored with proper extensions and obturation. The obturator should extend maximally up the lateral wall of the defect (Fig. 28.4). This high lateral extension increases retention and stability and helps recontour the lip and cheek.

The movement of the medial side of the ramus into the distolateral area of the defect must be accounted for during impression procedures. The extension superiorly along the medial margin of the defect should not exceed the level of the repositioned palatal mucosa or the floor of the nose. Further superior extension will impede normal nasal airflow during speech and breathing, and may result in unnecessary and painful ulceration of the respiratory mucosa lining the nasal septum. In some patients, extension across the nasal surface of the soft palate or into the nasal aperture may be necessary to provide acceptable retention.

The placement of osseointegrated implants dramatically improves function of the obturator prosthesis, particularly for edentulous patients.^{2,3} The most desirable locations are the premaxillary segment and the maxillary tuberosity (Figs 28.2 and 28.5). Careful attention must be paid to the design of the tissue bar. Fewer implant sites are available and the anterior-posterior spread of those placed into the premaxilla is limited, subjecting these implants to an increased risk

Fig. 28.4 Cross-section illustration showing peripheral extension of obturator against lateral wall of surgical defect. In total maxillectomy defect this peripheral extension will exhibit the greatest range of motion.

of implant overload if designs are implant supported as opposed to implant assisted. The authors suggest that occlusal rests be placed on the tissue bars (Fig. 28.2) and resilient attachments be attached to both ends of the bar. Implants are splinted together and this design directs the occlusal forces on the unresected side (where the patient will actually masticate) along the long axis of the implants (Fig. 28.2). Patients are advised to masticate on the unresected side. Forceful occlusion on the defect side will result in rapid wear of the attachments securing the obturator prosthesis to the tissue bar and may also result in bone loss around the implants, particularly the implant adjacent to the defect.

When the prosthesis is completed, speech and swallowing are restored to normal limits. Most prostheses require relining within the first year because of slow but continuous changes of the tissues on the periphery of the surgical defect.

For the edentulous patient who will be undergoing extensive resections involving most of the hard palate, the choice of prosthetic vs surgical reconstruction is dependent upon the availability of suitable implant sites. The data indicate that implants have been reasonably successful in this group of patients. In the

Roumanas report² 102 implants were placed in 26 patients with acquired maxillary defects secondary to resection of palatal and paranasal sinus tumors. Six patients with 19 implants were not available for follow-up because either the patient expired prior to second-stage surgery or they developed recurrence of their tumors. Of the 83 implants remaining for study, four were buried and one patient with one implant had not undergone second-stage surgery. Seventy-eight implants with known status were available for study. The implant survival rate for these 78 implants was 69.2%. The implant survival rates were 63.6% for the irradiated group (67.0% before radiation and 50% after radiation) (mean dose of 5000 cGy) and 82.6% for the non-irradiated group. Anterior implants demonstrated 2.7 times greater number of exposed threads than posterior implants.

If palatal or alveolar bone sites are not feasible implant sites, another option to consider would be the use of implants placed in the zygoma (zygoma implants). Zygoma implants, 30–50 mm long, have been employed successfully in patients with large or total palatotomy defects. In the UCSF report,⁴ 28 zygoma implants were placed in nine patients with large maxillary defects. Six implants failed (most in irradiated patients), and five of the patients were eventually restored with an implant-retained obturator prosthesis. When restoring total palatotomy defects these clinicians recommend that two implants be placed into each residual zygoma and that all four be splinted together with a tissue bar (Fig. 28.6). Landis reported on the use of 36 zygoma implants in 15 patients.⁵ Twenty-four conventional implants were also placed in oral sites in these patients. Twelve of the 15 patients presented status postresection of large tumors of the maxilla and three presented with congenital defects. Nine of the patients were edentulous. Six of the twelve oncology patients received

Fig. 28.5 Solitary implant in maxillary tuberosity of an almost total palatotomy defect.

Fig. 28.6 Zygoma implants. (a) Two are placed on each side. (b) All four implants are splinted together with tissue bar. Note accumulation of plaque and calculus. (c) Completed prosthesis. (d) Prosthesis in position.

chemotherapy and seven received radiation therapy during the course of their treatments. Radiation doses ranged from 45–61 Gy. Nine of the patients were edentulous. The prostheses were retained with telescopic crowns associated with, when necessary, angled abutments. Follow-up ranged from 13–102 months. Three zygoma implants were lost secondary to overloading and/or chronic infection and five others were removed secondary to resection of recurrent disease.

It is possible to obturate hard palate defects with free vascularized flaps and this may be desirable in potentially non-compliant edentulous patients with large defects who may have difficulty tolerating a large removable prosthesis. However, in almost all situations surgical reconstruction of such defects is undesirable and actually impairs oral function. Restoration of partially dentate patients with unilateral defects of the hard palate with vascularized flaps is contraindicated in almost all instances. These flaps distort the palatal contours and compromise the tongue space (Fig. 28.7). Bulky soft tissue flaps preclude replacement of missing dentition in many patients and lack of tongue space compromises speech articulation. In addition, secretions accumulate on the sinus side of the flaps. These secretions become crusted, and are subsequently colonized by microorganisms. These mucous crusts become odiferous and also cause local infections. Total palatal defects are the exception to this rule. Free flap selection should be governed by the need to create viable implant sites. Fibula free flaps are preferred and subsequently implants are placed and an implant-retained prosthesis is fabricated that replaces the dentition and restores normal palatal contours and, if

Fig. 28.7 Partial palatotomy defect obturated with a radial forearm flap. Palatal contours are excessive and speech articulation was affected.

necessary, restores the partition between the nasal and oral cavities.

Definitive soft palate prosthesis

Defects of the soft palate and velopharyngeal complex require different and more complex prosthetic treatment. Velopharyngeal closure normally occurs when the soft palate elevates and contacts the contracting lateral and posterior pharyngeal walls of the nasopharynx. When a portion of the soft palate or lateral pharyngeal wall is excised or when the soft palate is perforated, scarred, or neurologically impaired, effective velopharyngeal closure cannot occur. Speech becomes hypernasal, and normal swallowing is not possible. With a properly extended and contoured pharyngeal obturator, the patient will be able to re-establish velopharyngeal closure if a residual portion of the velopharyngeal muscular mechanism still exhibits some functional movement. The obturator must not interfere with breathing, impinge upon soft tissues during postural movements, or hamper the tongue during swallowing and speech.

The soft palate obturator remains in a fixed position in the nasopharynx and does not attempt to duplicate normal movements of the soft palate. The inferior surface of the obturator should be level with the hard palate contour, which in most patients is approximately the level of the anterior tubercle of the atlas. The inferior margin of the posterior surface of the obturator contacts Passavant's pad, if present, and extends approximately 10 mm superiorly into the nasopharynx. During breathing and the production of nasal speech sounds, the space around the obturator reflects the potential for muscular contraction. During swallowing and the production of other speech sounds, this sphincteric muscular network moves into contact with the stationary acrylic resin obturator, establishing velopharyngeal closure (Fig. 28.8). A correctly constructed obturator and one accurately positioned in the nasopharynx to properly interact with the residual velopharyngeal musculature, will result in the return of normal speech and swallowing.

In edentulous patients a conventional complete denture may lack retention which prevents the obturator prosthesis from effectively interacting with the residual velopharyngeal musculature. The addition of implants provides sufficient retention to ensure accu-

Fig. 28.8 (a) Soft palate defect. (b) Pharyngeal obturator prosthesis. (c) Prosthesis in position with the tissues at rest. (d) During contraction the obturator comes in contact with the residual velopharyngeal musculature and permits the production of normal oral sounds and swallowing.

rate positioning of the obturator prosthesis in relationship with the residual velopharyngeal musculature and will enable effective velopharyngeal closure and normal velopharyngeal function (Fig. 28.9).

Edentulous patients with unrepaired clefts or those who do not have adequate numbers of teeth to support and retain the prosthesis can also benefit from the use of osseointegrated implants.

Tongue-mandible defects

Disabilities resulting from tongue-mandibular resections include impaired speech articulation, difficulty swallowing, deviation of the mandible during functional movements, poor control of salivary secretions, and often cosmetic disfigurement. If the surgical wound is closed primarily (primary closure) the functional disabilities are compounded. Advanced tumors of the oral tongue and floor of the mouth often require extensive resection of soft tissue and adjacent mandible. This loss of bulk and mobility combined

Fig. 28.10 Patient following resection of lateral tongue, floor of mouth, and mandible. The fibula free flap failed. Note the resultant mandibular deviation.

Fig. 28.11 The mandible and the lateral third of the tongue have been reconstructed with a fibula free flap.

with the loss of motor and sensory innervation leads to misarticulation of most speech sounds, inability to control saliva, impaired mastication, and seriously impacts the patient's ability to manipulate complete dentures. Deglutition is less impaired, and most patients learn to swallow fairly efficiently unless they receive chemoradiation following their surgical resections. In addition, the motor and sensory innervation of the lower lip on the resected side is often compromised, further impairing speech, mastication, control of saliva, and use of conventional complete dentures.

If much of the mandible is removed and not reconstructed the remaining functional mandibular segment will be retruded and deviated towards the surgical side. When the jaw is opened this deviation increases. These factors, combined with impaired tongue function, prevent effective mastication. The severity and permanence of mandibular deviation varies (Fig. 28.10). However some patients can attain reasonable occlusal relationships, although some frontal plane rotation will be observed. It is, therefore, highly desirable to reconstruct the mandible at the time of tumor ablation with a free vascularized flap.

From the prosthodontic perspective the first priority, however, following surgical ablation, should be restoration of the soft tissue deficit, particularly reconstruction of the tongue. With proper use of free flaps, tongue bulk can be restored and the mobility of the reconstructed tongue (Fig. 28.11) results in acceptable speech, swallowing, and saliva control.⁶ The advantage of free tissue transfers (free flaps) over musculocutaneous flaps is the improved blood supply, enhancing wound healing and flap survival. Most important with regards to function, there is considerably less scarring associated with free flaps, which permits the residual tongue-flap combination to move laterally, elevate, and interact with the maxillary dentition and the palatal vault during speech, mastication, and swallowing. If large mandibular segments need to be restored, the fibula is the preferred donor site unless the soft tissue deficit is unusually large. The osteotomized fibula provides sufficient length and bulk of bone and osseointegrated implants can be placed to retain and support a prosthesis (Fig. 28.12). The authors tend to favor removable overlay prostheses with milled tissue bars in these restorations because this design allows for more flexibility with regard to development of proper lip and cheek contours and is more easily serviced in the event of damage to the prosthesis (Figs 28.12 and 28.13).

Fig. 28.12 Mandibular defect reconstructed with fibula free flap. Tongue, and hypoglossal and lingual nerves are intact. Flangeless overlay prosthesis. (a) Tissue bar milled to a 3° taper. (b) Overlay prosthesis. Clip housings incorporated within metal substructure. (c) Prosthesis in position.

Free bone grafts

Free grafts are rapidly being replaced by free vascularized flaps as a means of restoring mandibular discontinuity defects. These grafts are limited by the fact that most tumors leading to mandibular resections are malignant, and arise from the oral mucosa; they require extensive resection of the soft tissues of adjacent tongue, floor of mouth, and alveolus. Many other patients require postoperative radiotherapy or chemoradiation which further compromises the blood supply to the local tissues which must house the graft. In these situations either the volume of the residual soft tissues is insufficient to house the graft or the residual vasculature is insufficient to support the graft. However, free grafts can be effectively employed to restore mandibular continuity following resection of benign tumors such as ameloblastomas, when the resection is confined to the mandible itself.

Autogenous graft sources include iliac crest, rib, and clavicle. Most commonly the defects are restored either with particulate autogenous marrow housed in a metal tray or with a block of bone, both usually obtained from the iliac crest. The use of myocutaneous flaps for closure of the initial wound facilitates free bone grafting of continuity defects by enhancing the volume and vascularity of the recipient soft tissues. These grafts are excellent sites for placement of osseointegrated implants (Fig. 28.13). The long-term success rates of implants in free grafts exceeds 90% in most clinical follow-up studies.⁷⁻¹⁰

Free bone grafts demonstrate a homogeneous calcification pattern that results in excellent bone anchorage. Implant position should be prosthetically driven

and should be based on a diagnostic wax-up and a surgical template.

A major challenge is to create a zone of thin, immobile, and, if possible, keratinized tissue around the implants as the restoration emerges through the peri-implant tissues. If the peri-implant tissues are excessively thick and movable, these tissues are subject to hypertrophy and local infection. This is particularly an issue in patients reconstructed with free vascularized flaps, because the soft tissues overlying the bone may be up to 1 cm thick. Thinning of these tissues is best accomplished at second-stage implant surgery. A stent secured to the implant fixtures will facilitate healing following this procedure. Abutments emerging through skin must be highly polished to avoid peri-implant tissue inflammation and hypertrophy.

Free vascularized flaps

A major advance in mandibular reconstruction has been the development of improved techniques in microvascular surgery, which allow for composite grafting of larger volumes of tissue. In microvascular free tissue transfer (free flaps), bone, muscle, connective tissue, and skin can be autogenously grafted and remain viable. The grafting can be accomplished simultaneously with resection of the tumor, with excellent results.⁶

The composite fibula flap is the preferred donor site for most complex mandibular discontinuity defects but the surgeon must realize that the skin paddle may not always be sufficient for defects that involve significant portions of the anterior two thirds of the tongue. Multiple osteotomies may be per-

formed without devascularizing the bone segments, to replicate the arch of curvature of the replaced mandible. The contours of the fibula and its well developed cortices make it an excellent recipient of osseointegrated implants. Success rates of implants in free fibula grafts are generally above 90% in most clinical follow-up studies.¹¹ In this group of patients, the implant-retained restoration is most effective if there is sensory innervation remaining on the defect side, particularly the lateral border of the tongue. When the lingual nerve has been resected, or in patients where the lateral portion of the oral tongue is reconstructed with a free flap, the patient will be unable to detect and manipulate the food bolus, and, as a result, mastication will not be as efficient on the resected side. If such is the case and the patient has healthy dentition remaining in the unresected portion of the mandible, a removable partial denture is probably in the best interest of the patient.

Definitive prosthetic restoration

The functional outcomes of implant-retained prostheses for partially edentulous patients with resections of the tongue and mandible depend primarily upon the sensory status locally and the function of the residual tongue. In some patients with poor tongue function, only appearance and oral competence can be improved, while in others with good tongue function, mastication is a reasonable objective.^{12,13}

Complete dentures for edentulous patients with unrestored discontinuity defects of the mandible may provide esthetic improvement by replacing teeth and improving lip and cheek contours, but mastication is generally not possible even if the patient has reasonably good tongue control. A number of factors affect

the ability of these patients to masticate with so-called resection dentures:

- stability, support, and retention for the mandibular denture are compromised;
- compromised quality and quantity of saliva secondary to postradiation xerostomia;
- the angular pathway of mandibular closure, which induces lateral forces upon the dentures, tending to dislodge them;
- abnormal maxillomandibular relationships that may prevent ideal placement of the denture teeth over their supporting structures;
- impairment of motor and/or sensory control of the tongue, lip, and cheek, limiting the patient's ability to control dentures during function.

Implant-assisted resection dentures can overcome many of these difficulties, particularly those associated with compromised retention, stability, or support.

Implant-assisted overlay dentures

Patients with reasonable tongue bulk and mobility and with motor and sensory innervation intact on at least one side gain the most from implant-retained overlay dentures, whether the patient presents with either a resected or unresected discontinuity defect. The patients shown in Fig. 28.14 would not derive significant benefit from implant placement if improved mastication is the primary goal of the patient and the clinician. On the other hand, the patient in Fig. 28.15 would stand to derive significant benefit because his tongue has been reconstructed and has good mobility. In such patients mastication is improved because the tongue is no longer required to

Fig. 28.14 In both patients the mandible has been reconstructed but not the tongue. (a) Tongue immobilized. (b) Tongue unable to elevate to the level of the occlusal plane. Result: prognosis for mastication is very poor for both patients even if implants are employed to retain the lower denture.

Fig. 28.15 (a–c) Partial glossectomy defect restored with radial forearm flap. Portion of bearing surface resurfaced with flap. Movement of tongue is excellent. Prosthodontic prognosis is excellent, particularly if implants are employed to retain and stabilize the mandibular denture.

control the denture, and can be employed to manipulate the food bolus during mastication and swallowing. If the patient's speech is intelligible, this is a sign of good tongue mobility and control, and the prognosis for effective bolus manipulation and mastication with an implant-retained prosthesis is therefore going to be favorable (Fig. 28.15).

In unreconstructed discontinuity patients, if implants are to be placed into the mandible to retain and support an overlay prosthesis, consideration should also be given to placing implants in the opposing maxilla. The unilateral occlusal forces and increased lateral forces generated during the chewing cycle tend to dislodge the upper denture. In addition, xerostomia secondary to radiation therapy may compromise the peripheral seal of the maxillary complete denture. Therefore, implants should be considered if the retention and stability of a conventional maxillary denture is marginal (Fig. 28.16).

In most patients, the most favorable implant sites available in the edentulous resected mandible are located in the symphyseal region. A minimum of two implants should be placed. However, more may be desirable, if space allows. The authors prefer to splint the implants together and fabricate implant-assisted tissue bar designs for such defects in order to minimize the forces delivered to the implants. Examples of implant-assisted designs are shown in Figs 28.16 and 28.17.

Facial defects

Surgical reconstruction vs prosthetic restoration

Surgical reconstruction and prosthetic restoration both have limitations. The surgeon is limited by the availability of tissue, damage to the local vascular bed, and the need for periodic visual inspection of an oncologic defect. The prosthodontist is limited by movable tissue beds, and difficulties in retaining very large prostheses. The method of facial restoration should be considered before surgery, and patients should participate in the decision-making process and have realistic expectations.

Surgical reconstruction of small facial defects is preferable. However, it is difficult for the surgeon to contour a facial component that is as effective in appearance as a well made prosthesis. Osseointegrated implants in facial defects have changed patient perceptions about facial prostheses because of the retention achieved.¹⁴ Additionally, when a large resection is necessary and recurrence of tumor is probable, it is advantageous to be able to monitor the surgical site closely, which a prosthesis permits. Even when surgical reconstruction is deemed possible, most surgeons prefer to wait at least 1 year before surgical reconstruction. Also, surgical restoration of large defects is technically difficult and requires multiple procedures

Fig. 28.16 Mandibular discontinuity defect opposing the severely resorbed maxilla. (a) Implants placed into opposing maxilla to prevent tipping and loss of retention of maxillary denture during function. (b) Overlay prosthesis. (c) Prostheses inserted.

Fig. 28.17 When occlusal force is applied in extension area (x), prosthesis is designed to rotate around Hader bar (fulcrum line) into the posterior denture bearing surfaces, minimizing forces delivered to implants.

and hospitalizations, which may be further complicated if radiotherapy has been included.

Alterations at surgery to enhance the prosthetic prognosis

The key to creating esthetic facial prostheses is properly designed surgical defects. If surgical reconstruction of a facial defect following tumor ablation is not anticipated, several factors need to be addressed. The key to an esthetic facial prosthesis is to create a defect with minimal distortion of facial contours adjacent to the defect (Fig. 28.18). During nasal resections, the nasal bones should be resected and all raw tissue surfaces should be lined with split-thickness skin grafts. The anterior segment of the nasal septum should be removed and the anterior portion of the floor of the nose lined with skin. Primary closure of skin to mucosal margins should be avoided, for this practice distorts nasolabial folds, cheek and lip contours. In resections of the ear, total as opposed to partial resection is preferred. When possible however, the tragus should be retained because this structure will hide the anterior margin of the prosthesis. During orbital exenteration the eye lids should be removed and the orbit lined with a skin graft.

Covering facial defects with free flaps precludes the fabrication of prosthetic restorations in almost all situations and should be avoided.

Prosthetic facial restorations

The challenge to the prosthodontist is to fabricate an esthetically pleasing restoration. A conspicuous prosthesis may produce more anxiety and permit less social readjustment than a simple facial bandage or eye patch. The most critical period is the first 2–3 days after delivery. The patient must understand that a prosthesis has two different roles: for family, close friends, or business associates, it can only cosmetically replace the excised tissues; for the public at large, it generally provides enough concealment to render the reconstructed defect inconspicuous.

Materials and methods of retention for facial prostheses

Current materials all possess some undesirable characteristics.¹⁵ The materials most often used are the silicone elastomers, which have achieved wide clinical acceptance. Adhesives can be used to retain most facial prostheses but implant retention is preferred. Osseointegrated implants result in extremely well retained prostheses that permit vigorous physical activities. Patients favor implant-retained facial prostheses over adhesive-retained prostheses by a wide margin.¹⁴

Craniofacial implants

The use of osseointegrated implants has significantly improved patient acceptance of facial prostheses.¹⁴ The retention provided by implants makes it possible to retain large prostheses and makes it possible to fabricate thinner margins, which enhance esthetics by blending and moving more effectively with adjacent mobile tissues. Other benefits include elimination of the occasional skin reaction to skin adhesives, ease and enhanced accuracy of prosthesis placement, improved patient comfort, and decreased daily maintenance, which also increases the lifespan of the facial prosthesis.

Treatment planning

The implants must be positioned within the confines of the proposed facial prosthesis. In most patients it is desirable to sculpt a wax replica of the future prosthesis and to use this replica to fabricate a surgical template. This template is sterilized and used as a guide during surgery to ensure proper implant position and angulation (Fig. 28.19).

The number and arrangement of implants and possible bone sites are determined. In large extensive defects, computed tomography (CT) scans and three-dimensional models are useful in evaluating potential bone sites and important adjacent structures. The health of skin and soft tissues circumscribing osseointegrated implants is easier to maintain if these tissues

Fig. 28.18 (a) Favorable nasal defect. Nasal bones and anterior septum removed, raw tissues lined with skin. (b) Favorable auricular defect. Tragus retained. (c) Favorable orbital defect. Orbit lined with skin.

are thin (less than 5 mm thickness) and attached to underlying periosteum. If the skin contains hair follicles or scar tissue from past reconstructive procedures, these tissues should be removed and replaced with skin grafts.

Surgical placement

Craniofacial implant fixtures are fabricated from titanium. They are available in either 3 or 4 mm lengths, with a 5 mm diameter flange. The short lengths are designed to permit placement in areas with limited available bone. The flange facilitates initial stabilization of the implant and prevents penetration into interior components. For ear defects, two or three implants are positioned posteriorly and superiorly to the ear canal (Fig. 28.19). For nasal defects, the preferred fixture location is the anterior portion of the

floor of the nose (Fig. 28.20). Care should be taken to avoid the roots of the teeth in the area. For orbital defects, the preferred location is the lateral portion of the superior orbital rim.

Several attachment systems have been used to connect the facial prosthesis to the implants, such as bar-clips, magnets, and O-ring types. For auricular and nasal or large midfacial prostheses the authors prefer the bar-clip systems because they provide superior retention (Figs 28.20 and 28.21). They prefer magnetic retention for orbital prosthesis, because the ease of insertion of magnetically retained prostheses outweighs the possibilities of magnet corrosion and decreased retention over time. An acrylic resin substructure retaining the attachments is designed to fit within the contours of the silicone facial prosthesis. It should possess sufficient surface area so that the

Fig. 28.21 (a) Large facial defect with tissue bars. (b) Facial prosthesis. (c) Prosthesis in position.

bond between the acrylic resin substructure and the silicone prosthesis will not fail during insertion or removal of the prosthesis.

Success rates for auricular sites have exceeded 90% in most studies and few complications have been encountered. Success rates of the floor of nose sites are around 80%. Success rates in the orbit have ranged from 50–70%. Success rates are diminished if implant sites have been irradiated previously particularly in the orbit (Tables 28.1 and 28.2).¹⁶

Implants in irradiated tissues

Irradiation of head and neck tumors predisposes to changes in bone, skin, and mucosa, which affect the predictability of osseointegrated implants. The most significant of these changes are loss of vasculature and impaired function of osteoprogenitor cells in the marrow. Long-term function of osseointegrated implants is dependent upon the presence of viable bone that is capable of remodeling and turnover as the implant is subjected to stresses associated with supporting, retaining, and stabilizing prosthetic restorations. The viability of irradiated bone may not be sufficient to ensure a long-term predictable result, particularly in anatomic sites such as the supraorbital rim and the mandible. Even in the maxilla remodeling and turnover of bone subjected to high dose radiotherapy (above 5000 cGy) may be adversely affected to the point where an implant subject to functional stresses cannot be sustained.

When implants are considered for the irradiated patient several issues require careful consideration such as the risk of osteoradionecrosis, the potential benefit provided by the implants, the potential morbidity associated with implant failure, and the potential usefulness of hyperbaric oxygen.

Predictability of implants in irradiated bone

Preliminary reports and our own experience indicate that the success–failure rate of osseointegrated implants in irradiated bone appears to be dependent

upon the anatomic site selected, the dose to the site, and the use of hyperbaric oxygen. Animal experiments have shown that the bone-implant contact area is reduced at irradiated sites.^{17,18} In addition, Nishimura has shown that the quality of bone in the implant appositional zone is compromised, particularly at high radiation dose levels.¹⁹ In his study 44 adult New Zealand rabbits were assigned at random to six test groups. The animals received radiation to either the proximal or diaphyseal segments of both tibias. Equivalent doses ranged from 4000–7000 cGy. Three months following completion of radiation treatment, 5 mm screw-type implants were placed into each half of the left tibia of the surviving 38 rabbits. Polyfluorochrome labeling was performed 3 months postimplant placement and 2 days prior to sacrifice. Ground non-decalcified sections were prepared and evaluated. Results revealed a steady decrease in the label, especially when the equivalent dosage exceeded 5800 cGy, indicating reduced cellular activity. Also, when viewed under polarized light, the specimens receiving the highest radiation levels showed a preponderance of woven bone as compared to the dense lamellar bone seen in the controls and in specimens receiving lower doses.

The early trends seen in recent clinical reports appear to substantiate the concerns raised in the animal studies; namely, implants placed in irradiated maxilla and mandible have a significantly lower success rate.^{2,20–24} Implants in irradiated tissues used to retain facial prostheses appear to have a significantly lower success rate than implants in non-irradiated tissues (Tables 28.1 and 28.2).¹⁶ Roumanas reported on the results of 33 implants placed in the irradiated maxillae of 13 patients.² All patients received at least 5000 cGy to the implant sites. Eleven of the 33 failed and were removed and two others were buried beneath the mucosa for a success rate of 60.6%. Many of the remaining implants demonstrated moderate to severe bone loss (bone loss extending to at least the level of the fourth thread). In the mandible the success rates have varied from 65%²³ to 84%.²¹

Because of these results some clinicians^{20,23,25} have attempted to improve the viability of bone with hyperbaric oxygen treatments prior to implant place-

Fig. 28.22 (a) This patient received 6600 cGy for a squamous carcinoma of the lateral tongue. Three years later implants were placed. (b) Three years after implant placement the patient developed an infection associated with the left posterior implant. (c) Eventually, the patient developed an osteoradionecrosis and a pathologic fracture of the mandible; subsequently the mandible was resected. (From Beumer J, Sung E, Kagan R. 2004. Dental Management of the Irradiated Patient. An electronic program of instruction issued by the ISMR. Reproduced with permission.)

ment. Granström²⁰ treated 13 patients, who had previously been irradiated, with hyperbaric oxygen. Each patient received 20 treatments, implant surgery was performed, followed by 10 more hyperbaric treatments. Only one implant fixture was lost (2.0% of the total). In his most recent report Granström²³ reported only 29 implants lost of 349 placed in irradiated patients who received hyperbaric oxygen whereas 117 out of 291 placed in irradiated patients who did not receive hyperbaric oxygen were lost.

In summary, it is clear from the current data that osseointegration is impaired in bone that has received doses in excess of 5000 cGy. Success rates, based on short-term clinical reports, are reduced as compared to non-irradiated sites. The success rates are lower than in normal individuals even in the maxilla with its excellent blood supply. In addition, preliminary animal studies referred to previously appear to indicate that the bone–implant interface may be signifi-

cantly compromised making the implant less able to tolerate functional loads. Hyperbaric oxygen appears to help revitalize the bone, leading to improved success rates, but its high cost precludes its use in most patients.

Risk of osteoradionecrosis in the mandible is probably best determined by an analysis of the bone necrosis rate seen in postradiation extractions. Based on this data it should be relatively safe to place implants in irradiated mandibular sites if the dose is less than 5500 cGy. The risk would be quite high for doses above 6500 cGy (Fig. 28.22). In such patients, if implants are desirable, the authors recommend a course of hyperbaric oxygen as described by Granström.²³ In patients with doses to bone sites between 5500 and 6500 cGy, individual patient factors such as the dose per fraction, a previous radical neck dissection, and so on, may be important cofactors to consider when assessing the risk. In these

Fig. 28.23 (a, b) These implants were placed anterior to the field of radiation (note distribution of hair in patient's beard). (c) Implant-retained overlay denture. (d) Prostheses in position.

patients, if implants are considered elective they should be deferred. If implants are deemed essential, the authors recommend they be placed in conjunction with hyperbaric oxygen. It should be noted that most patients do not receive radiation to the symphyseal region. Therefore, implants can be placed with a high degree of predictability in this region (Fig. 28.23).

In the maxilla the risk of bone necrosis is probably negligible. The use of hyperbaric oxygen can be justified only on the basis of improving success rates.

Irradiation of existing implants

Irradiation of titanium implants already in place results in backscatter and, therefore, the tissues on the radiation source side of the implants receive a higher dose than the other tissues in the field. The dose is increased about 15% 1 mm from the implant (Fig. 28.24). Because of backscatter and the increased numbers of elderly patients receiving implants,^{26,27} clinicians ask if osseointegrated implants should be removed in patients about to be irradiated for head and neck tumors. Granström²⁰ addressed this question in his report of 11 patients with 33 existing titanium implants who were scheduled to be irradiated. Dosages ranged from 5000 to 6600 cGy. Based on his findings Granström²⁰ recommended that all abutments and superstructures be removed prior to radiation and skin and/or mucosa should be closed over

Fig. 28.24 Implants were placed simultaneous with tumor resection and reconstruction of this large body-symphyseal defect with a fibula free flap. The patient received 6000 cGy postoperatively. Several months later and just after delivery of the tissue bar, the tissues on the labial surfaces of the implants dehiscid and the bone overlying the implants sequestered leading to loss of the implants. The graft remained viable and mandibular continuity was maintained. (From Beumer J, Sung E and Kagan R. 2004. Dental Management of the Irradiated Patient. An electronic program of instruction issued by the ISMR. Reproduced with permission.)

the implant fixtures. When healing is complete, radiation therapy can begin. Following completion of radiation, abutments and the superstructure are reattached and the prosthesis remade or readapted.

Chapter 29

Infections of the Oral and Maxillofacial Region

Tomoari Kuriyama, Michael A.O. Lewis, and David W. Williams

The term “infection” is defined as the detrimental colonization of a host organism by a foreign microorganism, and “inflammation” is the term describing the host’s response to stimuli including those of infection. The onset of infection depends on the balance between the virulence of microorganism and the host’s defenses.¹ Infection resulting from microorganisms invading from outside of the host is termed as an “exogenous infection” whilst an infection caused by microorganisms already residing within the body is called an “endogenous infection”.

Oral and maxillofacial infections generally have the following characteristics: (1) the large majority are endogenous, and commonly involve microorganisms residing in the mouth; (2) the infections frequently originate from existing dental and periodontal diseases.

In this chapter, the etiology, clinical features, diagnosis, and treatment of bacterial, fungal, and viral infections in the oral and maxillofacial region are described. Infection related to salivary glands will be presented in a separate chapter.

Biomedical sciences

An overview of the basic concepts of biomedical sciences is necessary in order to fully understand the etiology and clinical features of oral and maxillofacial infection, and the implementation of appropriate clinical management.

Anatomy

Oral and maxillofacial bacterial infections often originate from dental diseases and sometimes spread to the jaw, fascial spaces, paranasal sinuses, and lymph nodes. A description of the anatomy of these structures is provided below.

Tooth

The tooth comprises enamel, dentin, cementum, and pulp (Fig. 29.1).² In terms of infection, concerns are perhaps greatest when there is involvement of the pulp. The pulp is the central part of the tooth, and is filled with soft connective tissue containing blood vessels and nerves that enter the tooth from a hole at the apex of the root. There are also accessory canals that branch from the main canal. The pulp fulfills a variety of roles including provision of nutrients to the tooth and formation of dentin. Teeth with pulp necrosis and those where the pulp has been completely removed by endodontic therapy are called non-vital teeth. The hard tissues of a non-vital tooth tend to weaken making them more likely to crack and break when compared with vital teeth. The color of non-vital teeth usually changes to a purple-gray, as the pulp dies and the blood cell components degenerate.

Periodontium (periodontal tissues)

The periodontium describes the specialized tissues that surround and support the teeth, thereby maintaining them within the bones. The four major tissues that comprise the periodontium are the gingiva, alveolar process (alveolar bone), periodontal ligament, and cementum (Fig. 29.1). The alveolar process is the bony portion of the maxilla and mandible where the teeth are embedded and through which the roots of the tooth are supported. The bones, including the alveolar process, consist anatomically of cortical and cancellous bone.³ The cortical bone is the outer

Fig. 29.1 Anatomy of tooth and tissues that surround and support the tooth.

compact layer and provides strength and rigidity. The cancellous bone is the inner spongy bone, which consists of a network of trabeculae arranged to resist external forces. The interstices of cancellous bone are filled with bone marrow. The thickness of cortical bone and density of cancellous bone in the mandible are greater than in the maxilla. A connective tissue membrane called the periosteum surrounds the bone. Periosteum is continuous with muscle attachments, joint capsules, and the deep fascia, and it provides the underlying bone with nutrition.

Fascia spaces

Fasciae are broad sheets of dense connective tissue and function to separate structures that pass over each other during movement and serve as pathways for the course of vascular and neural structures. Fasciae can be divided into two types, superficial and deep.⁴ Superficial fascia is a mixture of loose areolar and adipose tissues that unite the dermis of the skin to the underlying deep fascia. The deep fascia is a membranous layer of connective tissue around the muscles and other deep structures. Between the dense layers of deep fascia in the neck is a loose connective tissue that forms potential spaces that can be eroded or distended by blood, pus, purulent exudates, and air (gas). Thus, fascial spaces are the potential spaces that normally do not exist but become filled under special conditions, including those of infection or bleeding. The arrangement of the fascia determines the pattern of spread of infection. The locations of the most important fascial spaces are discussed later in the section Fascial space infections.

Paranasal sinuses

Paranasal sinuses are air-filled spaces within the bones of the skull and face. They exist bilaterally, and have four subgroups: the frontal sinuses, the ethmoid sinuses, the sphenoid sinuses, and the maxillary sinuses (Fig. 29.2).² These sinuses are lined with mucoperiosteum. Amongst the paranasal subgroups, it is the maxillary sinus that is perhaps the most significant for dentists and oral surgeons. The maxillary sinus is the largest of the paranasal sinuses, and it is pyramidal in shape. The maxillary sinus is very small at birth, but enlarges and becomes fully formed in adolescence (around 18 years of age).⁵ The maxillary sinus opens into the middle meatus of the nose through the hiatus semilunaris. The mucus produced by the glands of the mucous membranes is transferred to the nose by ciliary action of the columnar cells. Drainage of the mucus is also achieved by the siphon action created during nose blowing. The cilia and mucus play a significant role in draining foreign substances including bacteria from the sinus to the nasal cavity. The apices of the second maxillary premolar and the first and second molar teeth are located in close relation to the floor of the sinus and may be

separated only by mucous membrane and thus permit dissemination of agents from dental infection.

The lymph nodes

The lymph nodes are components of the lymphatic system. Lymph nodes act as filters, or traps, for foreign particles. When the host is fighting an infection, characteristic swelling of the lymph nodes may be observed (lymphadenopathy). The lymph nodes in the head and neck are made up of several regional groups and a terminal group. The regional groups comprise the occipital, retroauricular (mastoid), parotid, buccal, submandibular, submental, anterior cervical, superficial cervical, retropharyngeal, laryngeal, and tracheal nodes (Fig. 29.3).^{4,6} The terminal group of nodes receives all the lymph vessels of the head and neck, either directly or indirectly, via one of the regional groups. The terminal group is closely related to the carotid sheath and, in particular, to the internal jugular vein, and is referred to as the deep cervical group. Important lymph nodes for consideration by dentists are outlined below.

Fig. 29.2 Paranasal sinuses have four subgroups: the frontal sinuses, the ethmoid sinuses, the sphenoid sinuses, and the maxillary sinuses.

Fig. 29.3 Anatomic location of lymph nodes and lymph drainage of the head and neck.

Submandibular lymph nodes

These lymph nodes lie superficially to the submandibular salivary gland, just below the lower border of the body of the mandible. When enlarged, these nodes are easily palpable. The nodes receive lymph from a wide area including the front of the scalp, the nose, the cheek, the upper and lower lips (except the center part of the lower lip), the frontal, maxillary, ethmoid sinuses, the upper and lower teeth (except the lower incisors) and the associated gingiva, the floor of the mouth, and the vestibule. The efferent lymph vessels drain into the deep cervical lymph nodes.

Submental lymph nodes

Submental nodes are located just below the chin and above the body of the hyoid bone. When enlarged, these nodes are easily palpable. Submental nodes receive lymph from the tip of the tongue, the floor of the anterior part of the mouth, the incisor teeth and the associated gingiva, the center part of the lower lip and the skin over the chin. The efferent lymph vessels drain into the submandibular and deep cervical lymph nodes.

Deep cervical lymph nodes

The deep cervical lymph nodes form a vertical chain along the course of the internal jugular vein within the carotid sheath. When enlarged, these nodes are palpable. These lymph nodes receive lymph from neighboring structures and from all the other regional lymph nodes in the head and neck. The efferent lymph vessels from the deep cervical lymph nodes join to form the jugular trunk, which drains into the thoracic duct or the right lymphatic duct.

Microbiology

Numerous bacterial species survive within the body as commensal microorganisms. A commensal microorganism can be described as an organism that is often isolated from the body, but is rarely implicated in infection. It is not surprising therefore, that most commensal microorganisms have limited virulence. Within the community of the commensal flora, bacterial interactions will occur and a degree of stability in its composition will develop. Some microorganisms promote the growth and survival of other members by an inhibition of the host defense mechanisms, the provision of essential nutrients, and the modulation of the local environment to one more conducive to the survival of other organisms.^{1,7} On the other hand, the microflora can also exhibit microbial antagonism that suppresses the growth of its members through competition for essential nutrients and production of inhibitory substances. Microbial antagonism results in the prevention of overgrowth of potentially pathogenic microorganisms and the invasion of exogenous pathogens into the body. On occasions, however, members of the commensal microflora can be involved

in infections. Although the majority of infections involving commensal microorganisms are opportunistic, some infections, including odontogenic infections and sinusitis, occur even in individuals whose immunity is not significantly impaired.

The composition and features of the microflora vary between anatomical sites and the microbiology of the oral cavity, skin, and paranasal sinus is discussed separately.

Microbiology of the oral cavity

Over 500 bacterial taxa, several fungal species, some protozoan genera, and many viruses have been demonstrated to reside within the mouth, whilst numerous others are believed to remain undetected.⁸

Bacteria

Various host factors, including age, the presence or absence of teeth or prosthesis, periodontal status, medicine intake, systemic diseases, and lifestyle habits, can all influence the composition of the oral bacterial microflora.¹ Different sites in the oral cavity of one individual are also frequently colonized by different and distinct microflora.

Bacteria are by far the most predominant type of microorganism in the human mouth. Bacterial genera that are commonly found in the mouth are presented in Table 29.1. Members of viridans streptococci are generally the most predominant bacteria in the mouth, although the exact type varies with the intra-oral location.¹ Examples of viridans streptococci include *Streptococcus sanguinis*, *S. salivarius*, *S. mitis*, and the "*S. anginosus (milleri)* group". It should be noted that the genus *Streptococcus* is a very heterogeneous group of bacteria. *Streptococcus pneumoniae* and *Streptococcus pyogenes* are well known streptococcal pathogens of human infectious diseases. However, the pathogenicity and the antimicrobial susceptibility profiles of viridans streptococci are different from those of other streptococci.⁹

The oral environment of the neonate tends to favor aerobic and facultatively anaerobic bacteria.¹ Strictly anaerobic bacteria establish themselves with the formation of the gingival sulcus that results from tooth eruption. As sites with more anaerobic conditions appear, the number of strict anaerobes increases. In the case of strictly anaerobic bacteria, members of the genera *Fusobacterium*, *Porphyromonas*, *Prevotella*, *Veillonella*, *Actinomyces*, *Eubacterium*, and *Peptostreptococcus* are commonly recovered from the mouth. Some *Bacteroides* species including *B. forsythus* (*Tannerella forsythensis*), *B. ureolyticus*, and *B. distasonis* are also sometimes detected. These species have different pathogenic features and antimicrobial susceptibility profiles compared with the *Bacteroides fragilis* group. Although *Porphyromonas* and *Prevotella* species were formerly classified as *Bacteroides* species, these species are not bile-resistant organisms like *B. fragilis*, and their pathogenicity and antimicrobial

Table 29.1 Principal microbial genera/groups of the commensal human oral microflora.

Aerobic and facultative bacteria	Anaerobic bacteria	Fungi

	<i>Tanarella</i>	
	<i>Treponema</i>	
	<i>Aggregatibacter</i>	

susceptibility patterns are different from those of the *B. fragilis* group.

Since the subgingival environment is anaerobic, it will support the growth of strictly anaerobic microorganisms. The composition and bacterial quantity of the subgingival microflora will vary depending upon periodontal status.¹ Gram-positive cocci are predominant in the initial stage of periodontitis. Spirochetes appear as the condition develops and the proportion of strictly anaerobic Gram-negative bacilli also frequently increases. Most of the spirochetes detected belong to the genus *Treponema*, although numerous uncultivated species exist. The favored habitats of the oral *Treponema* species are the periodontal pockets.

Dental plaque is a biofilm that builds up on the teeth and consists of bacteria and their products all in close proximity to the surface of the teeth (Fig. 29.4). It is important to recognize that it is the bacteria in the plaque and not the saliva that cause dental caries and periodontal diseases. Since a biofilm structure affords protection to bacteria from antimicrobials and antibiotics, the effectiveness of administered antimicrobial mouthwashes can be diminished. Therefore, as is the case with other types of biofilms, the physical or mechanical removal (tooth-brushing and flossing) often represents the most effective way to control dental plaque. Although various bacterial species are present in dental plaque, the predominant type of bacteria varies depending on the intraoral location and the maturity level of the dental plaque. The proportion of oxygen-tolerant bacteria is higher in supra-gingival plaque than in subgingival plaque. In contrast, strict anaerobes are predominant in subgingival plaque. Plaque can calcify through the presence

**Fig. 29.4** Dental plaque.

of calcium and phosphorus in the saliva and the resulting calcified deposit is called calculus, within which there are no living microorganisms.

Yeasts

Up to 80% of healthy individuals harbor yeasts in their mouths.¹ The prevalence of yeast carriage and the actual numbers of yeast generally increase with patient age, although high numbers of yeast are also readily detected in the mouths of infants due to their relatively immature immune system.¹⁰ Colonization rates and quantity of yeasts are influenced by various factors.¹¹ Depression in normal host defense levels is undoubtedly a major factor. Oral status, denture wearing, reduction in saliva production, receipt of systemic antibiotics, and antifungal agents can also all influence the likelihood of yeast carriage and level.

Candida species, and in particular *Candida albicans*, are the predominant oral yeasts.^{9,11} In general, *C. albicans* has a higher pathogenic potential compared with other *Candida* species. Importantly, *C. albicans* is normally susceptible to most antifungal agents that are currently administered.¹² The majority of non-*albicans* *Candida* exhibit a lower degree of virulence. However, some species including *Candida glabrata* and *Candida krusei* can be highly resistant to antifungal agents, especially those belonging to the azole class of antifungals.^{12,13} Fungal infection by *Candida* is a classic example of human opportunistic infection. Fungal infections, including oral candidosis, do not occur in the vast majority of yeast carriers even if their yeast levels are elevated. However, if an imbalance between the host defense levels and *Candida* virulence expression occurs, then fungal infections may develop.

Viruses

Although virology of the oral cavity has not been fully clarified, most viruses are thought to be oral transients, present only during active infections or during asymptomatic carrier states. It is the herpes group (Herpesviridae family) that is most frequently associated with the human oral diseases. These viruses include human herpes simplex virus (HSV), cytomegalovirus, varicella zoster virus (VZV), and Epstein-Barr virus (EBV).⁹

HSVs are classified either as HSV-1 or -2. HSV-1 can be involved in infection of oral mucous membranes (oral herpes), although it can also be a cause of genital herpes. HSV-2 is involved in infections of the genitalia and is rarely encountered in the mouth. The transmission of HSV usually results from direct contact with infected secretions from the carriers. The prevalence of HSV-1 infection increases from childhood, and reaches 44–85% in later adult years.¹⁴ Its initial primary infection is followed by a latent infection of neuronal cells in the dorsal root ganglia, and subsequent viral reactivation is accompanied by viral excretion from the original mucocutaneous site of infection, with or without the concomitant appearance of clinical signs and symptoms. The secondary and recurrent form of HSV-1 oral infection is herpes labialis, more commonly referred to as cold sores.

VZV is the virus involved in chicken pox (varicella) and shingles (zoster). Normally, this virus is not detectable in the mouth. However, during infection, varicella zoster virus may be detected in the oral environment, and can even be detected after clinical symptoms have resolved. Significantly and in a similar fashion to HSV, VZV remains dormant in the nervous system of the host in the trigeminal and dorsal root ganglia. In some cases, VZV reactivates later in life producing a disease known as herpes zoster or shingles.

EBV is one of the most common viruses of humans, and is believed to be acquired via saliva during childhood. Individuals infected with EBV often become asymptomatic carriers throughout their lifetime. In certain individuals, EBV can however be involved in several diseases including infectious mononucleosis, lymphomas, and cancers.⁹

Microbiology of the skin

The surface of the skin itself comprises of several distinct environments. Some areas, such as the axilla and the perineum provide moist environments, which allow colonization by a large number of microorganisms. However, the majority of the skin's surface tends to be dry and, generally, the overall quantity of bacteria on the skin surface is much lower than in the mouth. Aerobes and facultative bacteria, including *Staphylococcus epidermidis* and *Corynebacterium* species, are predominant, whilst some strict anaerobes, in particular *Propionibacterium* species, are also found colonizing the skin (Table 29.2).^{7,9,15}

Microbiology of the paranasal sinuses

The microbial flora of the paranasal sinuses commonly includes *Corynebacterium* species, *Haemophilus influenzae*, *Haemophilus parainfluenzae*, staphylococci, viridans streptococci, *Moraxella* species, and *Streptococcus pneumoniae* (Table 29.3).^{15,16} In addition, strict anaerobes including *Prevotella*, *Fusobacterium*, and *Propi-*

onibacterium species can also be recovered from non-inflamed maxillary sinuses.

Immunity and inflammation

Host defense systems

Although host defense systems have not been fully elucidated, our understanding of host immunology has increased greatly in recent years. In this section, the general concepts of host defense systems are concisely described.^{1,3,7,17–19}

Local barriers against infection

Skin, mucous membranes, saliva, and the commensal microbial flora act as local defense systems, and provide the first barriers against pathogens through mechanical, chemical, and biological processes. The epithelial lining is the principal mechanical barrier at all body sites exposed to the external environment.

Dryness may limit the overgrowth of certain microorganisms on the skin, whilst lactic acid and fatty acids in sweat and sebaceous secretions, and their low pH, can inhibit the long-term survival of bacteria. Saliva and mucus not only remove microbes through a mechanical flushing effect, but also contain antimicrobial peptides such as lactoferrin, lysozyme, and immunoglobulin A. The resident microbial flora serve as biological barriers to incoming microorganisms. The normal microflora exhibit an inherent

microbial antagonism that suppresses the growth of many potentially pathogenic microorganisms by competition for essential nutrients and the production of inhibitory substances.

Immune system

Once a pathogen breaches the primary barriers and invades into the body, the immune system responds immediately. The most important role of the immune system is to distinguish between “self” and “non-self” molecules that have entered into the body, and to trigger a series of immune responses. A molecule that stimulates an immune response is called an antigen. Proteins and polysaccharides that are constituents of a microorganism, such as surface coats, capsules, cell walls, flagella, and toxins of bacteria and viruses, are representatives of antigens, as are non-microbial exogenous substances, such as pollen, proteins contained in food, and transplanted tissues.

Various types of host cells and proteins are involved in the immune system. The immune system can be divided into humoral and cell-mediated immunity in terms of the components, but in practice there is substantial overlap.

- *Cell-mediated immunity.* Cell-mediated (cellular) immunity is defined as the protective function of immunization associated with cells. Cell-mediated immunity primarily involves leukocytes (white blood cells). The leukocytes consist of neutrophils,

eosinophils, basophils, monocytes (macrophages), and lymphocytes (B-cells, T-cells, and natural killer cells) (Table 29.4). Macrophages are monocytes that migrate from the bloodstream to the tissues, and are present throughout the body. Dendritic cells, which are derived from the bone marrow, are also involved in cell-mediated immunity where they play a key role in the processing and presentation of certain antigens.

- *Humoral immunity.* The immune system is the protective function of immunization mediated by protein components in the cell-free body fluid or serum. The complement proteins are also prime components of humoral immunity. Antibodies are produced by B-cells mediated by signals from T-cells, and bind specifically to certain antigens.
- *Complement.* The complement system is a biochemical cascade that helps clear pathogens from an infected individual. This system consists of a group of more than 20 plasma proteins and protein fragments, which normally circulate as inactive zymogens. Many kinds of microbes directly activate the complement system through the so-called alternative pathway. This pathway contrasts with complement activation mediated by antibody–antigen interaction, and this latter type of reaction is referred to as the classical pathway. Activation of the complement system is a cascade reaction. Similar to the coagulation cascade, one component of the reaction triggers off the activa-

Table 29.4 The subtypes of human leukocytes and their functions.

Subtypes	% in blood	Functions/properties
Neutrophils	52–64%	Phagocytosis Initial responders to microbial infection Also called polymorphonuclear leukocytes (multi-lobed nucleus which appear like multiple nuclei) Short-lived cells Dead neutrophils are components of pus
Eosinophils	0–3%	Involved in protecting against parasitic infections and allergic reactions
Basophils	0–1%	Involved in allergic response by releasing the chemical histamine
Lymphocytes	30–40%	Divided into three types: B-cells: B-cells are produced and mature in the bone marrow. B-cells produce antibodies T-cells: T-cells mature in the thymus Helper T-cells manage and control immune responses Cytotoxic T-cells eliminate virus-infected and tumor cells NK cells: NK cells patrol throughout the body and combat tumor cells and cells infected by viruses
Monocytes	1–9%	Monocytes (macrophages) are located in the blood and become tissue macrophages after migrating from the bloodstream Phagocytosis Remove dead cell debris Present processed antigens of pathogens to T-cells (acts as activators of adaptive immune systems) Unlike neutrophils, macrophages have a longer active life

Table 29.5 Summary of differences between innate and adaptive immunity.

	Innate immunity	Adaptive immunity
Specificity of reaction	Non-specific	Specific for each pathogen
Onset of response	Immediate after antigen exposure	Lag time between exposure and maximal response
Involved components	Cellular and humoral components	Cellular and humoral components
Immunological memory	No	Yes

tion of subsequent members in the complement pathway. Unlike antibody, binding of complement to antigen is a non-specific reaction.

All components of the immune system are associated with the recognition of antigen, presentation of antigen information to other components of the immune system, and the destruction and elimination of the pathogen. The actions of the immune response do not occur independently and close interaction between processes takes place.

The immune system can be divided into innate and adaptive immunity (Table 29.5 and Fig. 29.5). It is the innate immunity that first responds and combats a pathogen that has invaded the body. Innate immunity does not require previous exposure to a pathogen. Activation of adaptive immunity follows innate immunity, its effect is more specific to the targeted pathogen, and often “memory” of the pathogen occurs following a successful adaptive response.

**Fig. 29.5** Mechanism of immune response.

Innate immunity

The innate immune response occurs immediately after pathogens enter the body and is not specific to any particular pathogen. Innate immunity requires no previous exposure to a pathogenic organism. The major roles of the innate immune response are the elimination of pathogens and the activation of adaptive immunity. Macrophages, neutrophils, natural killer cells, dendritic cells, and the complement system play a significant role in innate immunity.

The most important role of the cellular components in innate immunity is phagocytosis. Phagocytes are cells that have the ability to phagocytose microorganisms or other cellular targets. Key phagocytotic cells are macrophages, neutrophils, and dendritic cells. Phagocytes normally patrol the body searching for pathogens. During infection, these cells are recruited to the site of pathogen invasion.

When tissues have been damaged by microbes or toxins produced by microbes, various cells including macrophages present at the infection site release cytokines, which are soluble proteins and peptides that mediate communication between different types of cells. Cytokines trigger the onset of inflammation (the pathology of inflammation is described later). Initially, circulatory disturbance and exudation of plasma and cellular components from blood vessels in the infected tissue occur. Phagocytes travel to the infection site in response to the release of cytokines by host cells. During the initial stages, neutrophils, which are the predominant subtype of leukocytes, are the primary phagocytes. These cells first attach to the endothelial lining of the blood vessel and, by a process referred to as diapedesis, exude from the vessel, migrating towards the inflammation site. Phagocytes are short-lived cells and will soon die after engulfing and killing pathogens. The dead neutrophils are the major constituents of pus.

The complement system is the humoral component of innate immunity. It has three major roles: (1) complement proteins adhere to the surface of microbes (antigen) to enhance leukocyte phagocytosis, a process called opsonization; (2) the complement system activates the movement of leukocytes to the infection site; (3) complement directly damages the pathogens through contact with their cell surface.

Natural killer cells are cytotoxic and large granular lymphocytes with a characteristic morphology and cytotoxic functional role. Natural killer cells normally patrol throughout the body and once they

encounter tumor cells and cells infected by viruses, the natural killer cells destroy the target cells by releasing small cytoplasmic granules of proteins which trigger apoptotic killing. Therefore, natural killer cells play a major role in the prevention of tumor development and spread of viral infection.

The presentation of antigen to lymphocytes is another major role of innate immunity. Macrophages, dendritic cells, and cytokines are primarily associated with this role. These cells present antigen to lymphocytes (T-cells), which are key cells of the adaptive immune system. Although innate immunity itself plays an important role in defense, it therefore also acts as an activator of adaptive immune systems.

Adaptive immunity

When innate immunity is insufficient to defend against invasion of pathogens, the adaptive immune system, which is a specific and strongly defensive reaction, is triggered. There is generally a time lag between exposure and maximal response, because of the requirement to be activated by the innate immune system. The major functions of the adaptive immune system include the recognition of specific (non-self) antigens during the process of antigen presentation, the generation of responses that are tailored to maximally eliminate specific pathogens or infected cells, and the development of immunological memory, which allows rapid elimination of the pathogen during subsequent exposure to the organism.

Lymphocytes are a key subtype of leukocyte cells involved in the adaptive immune system. The peripheral blood contains 20–50% of all circulating lymphocytes, and the rest circulate within the lymphatic system. B-cells and T-cells are subclasses of lymphocytes. B-cells are produced and matured by stem cells in the bone marrow; whilst T-cells travel from the bone marrow to the thymus where they mature. Immature T-cells develop into several mature types when the adaptive immune system is triggered. Helper T-cells (CD4+ lymphocytes), play an important role in establishing and maximizing the capabilities of the adaptive immune response. These cells lack cytotoxic or phagocytic activity so they do not kill either infected cells or eliminate pathogens directly. However, helper T-cells manage and control the immune response by directing other cells to perform these tasks. Once helper T-cells have received and recognized the antigens, they secrete cytokines that induce activation of many types of cells associated with host defense, including macrophages. The cytotoxic T-cell (killer T-cell; CD8+ lymphocyte) is another major type of mature T-cell. Cytotoxic T-cells perform the function of eliminating cells infected with viruses, and damaged or dysfunctional cells.

B-cells are involved in the production of antibodies that circulate in blood plasma and lymph, and play an essential role in humoral immunity. Antibodies (immunoglobulin, Ig) are large Y-shaped proteins that serve to identify and neutralize foreign

antigens. There are five basic types of antibody (IgA, IgD, IgE, IgG, and IgM), which can be distinguished by biological properties. B-cells identify pathogens when the cell's surface antibodies bind to the specific target antigen. The antigen–antibody complex is processed into peptides and the B-cells subsequently display these antigenic peptides on their surface to attract helper T-cells. The helper T-cells release cytokines (lymphokines) and activate the B-cells, and, as a result, enormous amounts of the specific and required antibody are produced. The antibodies bind to pathogens expressing the antigen and “mark” them for destruction by complement activation or for specific destruction by phagocytes. Antibodies also neutralize challenges directly by binding to bacterial toxins or by interfering with the receptors that pathogens use to infect cells.

Some members of B-cells and T-cells ultimately mature into memory cells. These memory cells form a database of effective B- and T-lymphocytes; upon interaction with a previously encountered antigen, the appropriate memory cells are selected and activated. Consequently a stronger immune response can be produced quickly during second and subsequent exposures to that particular antigen.

Compromised host defenses and association with infection

As described earlier, infections in oral and maxillofacial regions are opportunistic. A compromised host defense increases the likelihood of infection, and provides an elevated risk of extensive progression and a probable prolonged period before resolution. Various congenital and acquired factors can compromise the host defense mechanism. Bacterial infection is generally associated with cellular and/or humoral immunity defects, whilst fungal and viral infections are thought to largely relate to cellular immunity defects.

Inflammation

Pathology of inflammation

It is widely accepted that inflammation is one of the manifestations associated with the host response to maintain biological homeostasis against stress. A variety of factors, including microbial, physical, and chemical stimuli, can be the origin of this stress. In oral and maxillofacial infections, microbes or their toxins initiate a series of inflammatory reactions. Although the inflammation itself is protective for the host, it sometimes acts harmfully or leads to unwanted damage to the host. Swelling, redness, pain, heat, and loss of function are all classic signs of inflammation. Inflammation that is short term is described as an acute inflammation, whilst a prolonged period of inflammation is referred to as chronic inflammation.³

Once inflammation has been triggered by certain harmful stresses, circulatory disturbance will ensue. As a consequence, the dilation of blood vessels (vasodilation) and congestion occurs following the initial

constriction of the vascular smooth muscle. Moreover, alteration of endothelium results in elevated vascular permeability (vasopermeability). Vasopermeability leads to exudation of plasma from blood vessels and a resulting increase in blood viscosity. The increase in vasopermeability allows the exudation of plasma containing albumins, globulins, and fibrinogen, and the extravasation of leukocytes (mainly polymorphonuclear leukocytes) through the endothelium and basement membrane of the blood vessel into the tissue at the infected site. Exudation of plasma fluid induces inflammatory swelling (edema). The leukocytes migrate along a chemotactic gradient to reach the target foreign bodies, such as microbes, involved in the infection. The majority of exudated leukocytes in the initial stages of inflammation are neutrophils, and macrophages and lymphocytes emerge relatively later.

Through a series of reactions, a variety of biochemical cascade systems associated with inflammatory mediators (e.g. histamine, serotonin, prostaglandin, leukotriene, and bradykinin) act to propagate and mature the inflammatory response. These cascade reactions include the complement, coagulation, and fibrinolysis systems. The mediators are derived from plasma substances or directly from cells, and some of them are involved in the onset of pain.

The final act of the inflammatory process is proliferation of cells at the injured site. Monocytes, lymphocytes, fibrocytes, and vascular endothelial cells are recruited to the site of tissue damage where they play an important role in angiogenesis and tissue repair with the formation of granulation tissue.

Removal of the cause of injury generally halts the response of the inflammatory mechanisms. Acute inflammation generally terminates without obvious proliferation of cells. However, in cases where inflammation fails to restore homeostasis, chronic inflammation will ensue. Chronic inflammation is characterized by simultaneous destruction and healing of the tissue.

Clinical signs of inflammation

Most symptoms of oral and maxillofacial infections result directly from the inflammatory reaction.

Local signs

The classic signs of inflammation include swelling, redness, pain, heat, and loss of function (dysfunction) (Table 29.6). Swelling results from circulatory disturbance (edema) and in the case of chronic inflammation, proliferation of cells may be also associated. The redness and heat result from the circulatory disturbance, in particular congestion. Several factors are related to the onset of pain. Some inflammatory mediators, such as prostaglandin, change in tissue pH, and physical stress to nerves resulting from swelling may be involved. In the case of bacterial infection, intensity of pain generally depends on the pressure of fluid within the tissue. Pain and swelling

Table 29.6 The relationship between classic signs and symptoms of acute inflammation and pathological change.

Signs and symptoms	Association with pathological change
Redness	Circulatory disturbance (congestion)
Heat	Circulatory disturbance (congestion)
Swelling	Circulatory disturbance (edema), proliferation of cells
Pain	Release of inflammatory mediators, change in pH of tissue, physical stress to nerve
Function loss	Pain and swelling, inappropriate proliferation of cells, tissue destruction

are major causes of dysfunction, although inappropriate proliferation of cells and tissue destruction resulting from the inflammatory reaction can be involved in loss of function. Trismus is the term describing inability to open the mouth normally. It is the most common oral dysfunction and is largely due to inflammation of the masseter and other masticatory muscles.

Systemic signs

Infection affects the host systemically and results in the expression of various systemic reactions. Fever, an increase in pulse rate, and fluctuation in hematological components are prime examples of subsequent systemic responses to infection.

- **Fever.** Fever is defined as an increase in internal body temperature to levels that are above normal, and often results from the systemic effects of inflammation. Variations in normal body temperature between individuals are not uncommon. Various non-pathogenic factors, including the time of day, location, situation within which the temperature is being measured, age, gender, and the stage of menstrual cycle, may also influence body temperature. Body temperature is also different at various sites within the same individual and is most frequently measured within the mouth, axilla or rectum. Fever results from an elevated thermoregulatory set-point regulated in the hypothalamus. A substance that induces fever is called a pyrogen. Pyrogenic agents may be endogenous or exogenous.^{3,7} The lipopolysaccharide (LPS; endotoxin) that is a cell wall component of Gram-negative bacteria is representative of a typical exogenous pyrogen. The LPS molecule may directly affect the hypothalamic thermoregulatory center. With regards to endogenous pyrogen, some cytokines including interleukin (IL)-1 and IL-6 that are released by macrophages following exposure to bacterial endotoxin, viruses or lymphocyte products stimulate prostaglandin E₂ (PGE₂) synthesis in the hypothalamic thermoregulatory center.⁷ As a result, the thermoregulatory center that controls

body temperature is altered. The majority of non-steroidal anti-inflammatory drugs block the fever response by inhibiting cytokine (IL-1)-stimulated PGE₂ synthesis in the hypothalamus.

- **Elevation in pulse rate.** A normal pulse rate for a healthy adult under resting conditions is around 60 beats per minute, although it ranges widely between individuals and fluctuates due to various non-pathogenic factors. The pulse rate in patients with infection or inflammation is generally seen to increase and is also associated with an elevation in body temperature.
- **Fluctuation in haematological data.** Infection may influence various components of the blood:
 - **Leukocytes.** Leukocytes, especially neutrophils, play a prime role in the elimination of causative agents of infection. The bone marrow supplies large numbers of these cells to combat infection. An elevation in the blood leukocyte count (leukocytosis) is frequently seen in cases of bacterial infection and tissue injury, and is triggered by specific mediators (IL-1 and tumor necrosis factor (TNF)- α) released by macrophages and other cells. In the case of more severe infection, an increase in immature neutrophils, which results from irritation of the bone marrow with regeneration or insufficient response of the bone marrow to the host's demand on production of more leukocytes, may be observed. This is referred to as a left shift (Fig. 29.6).
 - **Serum protein.** In the initial stage of infection, IgM production may be promoted, and subsequently, levels of IgG and IgA may be elevated. C-reactive protein (CRP) is produced by the liver in the acute phase of an infection.²⁰ CRP was originally discovered as a substance bind-

ing the C polysaccharide of *Streptococcus pneumoniae*. Although its function has not been fully elucidated, it is thought to play an important role in immune systems.²¹ As CRP levels rise during inflammatory processes, it is readily detectable for diagnostic purposes.

- **Erythrocytes.** Notable fluctuation in the erythrocyte count does not occur during infection. The erythrocyte sedimentation rate (ESR) is the rate at which erythrocytes fall when anticoagulated blood is placed in an upright tube. The ESR is measured in mm/h and generally increases in the presence of infection or inflammation. The effect probably arises due to an elevated production of fibrinogen and an increase in blood viscosity as a result of inflammation.

Pharmacology

Various kinds of medicines may be used for management of oral and maxillofacial infections: this section discusses antibiotics, antifungals, antivirals, and analgesics.

Antibiotics

Antibiotics are substances produced by various species of microorganisms (bacteria and fungi) that suppress the growth of other microorganisms and eventually may destroy them. However, common usage often extends the term "antibiotics" to include synthetic antibacterial agents, such as the sulfonamides and quinolones that are not the products of microbes. It is important to recognize that antibiotics work selectively against microorganisms, and that they are different from disinfectants and antiseptics

Fig. 29.6 An increase in the number of immature neutrophil band cells in the peripheral blood, is commonly seen in the course of an active infection. This is because of an insufficient response of the bone marrow to the host's demand on production of more leukocytes.

which can have a high toxicity both to human cells and the microorganism.

General considerations

Antibiotics are classified into bactericidal and bacteriostatic agents based upon their antimicrobial properties. Bactericidal agents directly kill bacteria, whilst bacteriostatic agents interfere with reproduction of bacteria and subsequently it is the host immune system that eliminates the bacteria.²² In general, the activity of antibiotics that inhibit cell wall synthesis by bacteria is bactericidal. Although the majority of antibiotics inhibiting synthesis of bacterial proteins have bacteriostatic activity, some do exhibit bactericidal activity (Table 29.7). Although use of bactericidal agents has been recommended for treatment of acute infections in oral and maxillofacial regions, their clinical effectiveness is not notably different from that of bacteriostatic agents when administered to patients with normal host defense mechanisms.

The *in vitro* activity of antibiotics can be expressed using the minimal inhibitory concentration (MIC) determined against target bacteria. An antibiotic that exhibits a low MIC is generally regarded to be effective against the target organism, as the growth of bacteria should be inhibited by low antibiotic concentrations. The pharmacological properties of antibiotics are also important, however. The antibiotic concentration achieved at the infected site must exceed the MIC for the target bacteria but not cause significant toxicity to the host. Antimicrobial agents can be divided into two main groups, based on antimicrobial pharmacodynamic characteristics: (1) agents that exhibit time-dependent bactericidal activity that

have little relationship to the magnitude of the drug concentrations, as long as the concentrations are above a minimally effective level (e.g. β -lactam antibiotics, macrolides, tetracyclines, and vancomycin); (2) agents that exhibit concentration-dependent bactericidal activity over a wide range of drug concentrations (e.g. aminoglycosides and fluoroquinolones). Some kinds of antibiotics have prolonged persistent effects (postantibiotic effect) in which the bactericidal action continues for a period of time after the antibiotic level falls below the MIC. Time-dependent antibiotics tend to have minimal to no postantibiotic effect, whilst concentration-dependent antibiotics usually have an associated dose-dependent postantibiotic effect. However, although the antimicrobial action of macrolides and tetracyclines is time-dependent, these antibiotics also have concentration-dependent features because of the occurrence of a relatively large postantibiotic effect.^{22,24}

The intervals for drug administration are determined in accordance with drug metabolism and pharmacokinetics. For concentration-dependent antibiotics, a high once-daily dose could be the best way to eradicate pathogens unless it causes significant toxicity. In contrast, in the case of time-dependent antibiotics, it is necessary to maintain the serum concentration above the MIC for at least 40–50% of the dosage interval.²⁵

Classes and characters of antibiotics

Antibiotics are usually classified based on chemical structure (Fig. 29.7). The following antibiotics are considered to have significance in the oral and maxillofacial surgical field.

Table 29.7 The properties of antibiotics that may be used in the management of oral and maxillofacial infections

Antibiotic	Antibacterial action	Pharmacodynamic category	Notable side-effects	FDA pregnancy risk categories*
Penicillins	Bactericidal	Time-dependent	Hypersensitivity	B
Cephalosporins	Bactericidal	Time-dependent	Hypersensitivity	B
Carbapenems	Bactericidal	Time-dependent	Hypersensitivity	B (Imipenem, C)
Macrolides	Bacteriostatic	Time-dependent	Drug interaction	B (Clarithromycin, C)
Clindamycin	Bacteriostatic	Time-dependent	Diarrhea, pseudomembranous colitis	B
Tetracyclines	Bacteriostatic	Time-dependent	Discoloration of teeth	D
Aminoglycosides	Bactericidal	Concentration-dependent	Nephrotoxicity, ototoxicity	D
Fluoroquinolones	Bactericidal	Concentration-dependent	Arthralgias, damage, drug interaction with NSAIDs	C
Glycopeptides	Bactericidal	Time-dependent	Nephrotoxicity	C
Metronidazole	Bactericidal	Concentration-dependent	Headache, nausea, disulfiram-like effect	B

* Pregnancy risk categories provide by the US Food and Drug Administration (FDA).²³

A, Controlled studies show no risk.

B, No evidence of risk in humans.

C, Risk cannot be ruled out.

D, Positive evidence of risk.

X, Contraindicated in pregnancy.

Fig. 29.7 Target sites of antibiotics.

β-lactams

β-lactam antibiotics have been widely used in the prevention and treatment of a variety of human infections. Although β-lactam antibiotics can be classified into penicillin, cephalosporin, carbapenem, and monobactam classes, all have a chemical structure called a β-lactam ring, and have bactericidal activity by binding to penicillin-binding proteins (PBP) and inhibiting synthesis of the bacterial peptidoglycan cell wall.^{7,26}

β-lactam antibiotics are generally regarded to be safe agents, because they target the cell wall in bacteria, which does not exist in human cells. However, hypersensitivity to antibiotics should be considered. The most likely form of hypersensitivity is a dermatological reaction. It should be noted that anaphylactic reaction is rare, but under certain conditions it can be serious and lead to a fatal hypersensitive reaction.

Bacterial resistance against the β-lactam antibiotics is increasing at a dramatic rate.^{27,28} The mechanisms of resistance include: (1) production of β-lactamases, which are bacterial enzymes that hydrolyse the β-lactam antibiotic; (2) expression of an altered PBP; (3) decreased antibiotic entry or active effluxing of the antibiotic from the bacterial cell.^{26,29}

- **Penicillin.** The penicillin class of antibiotics has a long history, and remains one of the most important antibiotics, although numerous other antimicrobial agents have been produced since the first penicillin was discovered in 1928 by Alexander Fleming. Members of the penicillin group have minimal direct toxicity. Hypersensitivity reactions are the most common adverse effects. Overall incidence of the reactions to penicillins varies from 0.7–10% in different studies. Hypersensitive reactions may occur with any dosage form of

penicillin. Penicillin G, penicillin V, ampicillin, and amoxicillin are commonly used for oral and maxillofacial infections, because of their historical effectiveness and minimal toxicity. Penicillin G and penicillin V have a narrower spectrum of activity than ampicillin and amoxicillin. The gastrointestinal absorption and peak serum level of amoxicillin are excellent, whilst the financial cost is higher compared with the other members.

- **Cephalosporin.** The cephalosporin class of antibiotics is another important group of β-lactam antibiotics. Some of the older antibiotics have a relatively narrow spectrum, but newer antibiotics generally possess a broader spectrum of activity and have higher stability against various types of β-lactamases. Cephalosporin antibiotics are classified into four generation classes.²⁶ The first-generation agents have good activity against Gram-positive bacteria such as streptococci and staphylococci and relatively modest activity against Gram-negative bacteria. This class includes cefazolin and cephalexin. The second-generation agents have somewhat increased activity against Gram-negative bacteria but have weaker activity against Gram-positive bacteria compared with the first-generation agents. Cefuroxime, cefaclor, cefpodoxime, and cefmetazole are good examples of such antibiotics. The third-generation cephalosporins are generally even less active against Gram-positive bacteria than the second-generation agents, whilst they are much more active against Gram-negative bacteria including some β-lactamase-producing organisms, such as *Pseudomonas aeruginosa* and *Enterobacter* species. Cefotaxime, ceftriaxone, cefoperazone, and cefdinir belong to the third-generation agents. Although the fourth-generation cephalosporin antibiotics have a similar spectrum to the third generation agents, these agents are more stable to some extended-spectrum β-lactamases. Cefepime is regarded as a fourth-generation agent. It is worth highlighting that although the stability of the third- and fourth-generation cephalosporin antibiotics is high against many types of β-lactamases, the β-lactamase produced by *Prevotella* species (a major pathogen of orofacial infections) hydrolyses most cephalosporin antibiotics, regardless of agent generation.^{30,31} The toxicity level of cephalosporin antibiotics is low. However, as with penicillin, hypersensitivity is the most commonly found side-effect, and the incidence of allergic reaction is reported to be 1–3% of patients who are exposed.³² The majority of allergic reactions to cephalosporins are rashes, although anaphylaxis can occur. Due to the similarity in structure of penicillin and cephalosporin groups, patients who are allergic to one class of these agents may manifest cross-reactivity when a member of the other class is administered. In general, the likelihood of cross-reactivity of the second-, third-, and fourth-generation

cephalosporins with penicillin is lower than that of the first-generation cephalosporins.³² It should be noted that concomitant penicillin and cephalosporin allergy is not always due to cross-reactivity, as penicillin-allergic patients have a three-fold higher rate of allergic reactions to any drug, even structurally unrelated agents.³² Therefore, the histories of "penicillin or cephalosporin allergy" reported by patients might not be actually due to immunologic drug-related side-effects. The increased risk of an allergic reaction to certain cephalosporins in penicillin-allergic patients may be smaller than previously postulated, and 5–10% of penicillin-allergic patients have allergy to cephalosporins.³³ There is controversy over clinical use of cephalosporin in penicillin-allergic patients. Evidence-based guidelines provided by the American Academy of Pediatrics, have recently endorsed the use of cephalosporin antibiotics for patients with reported allergies to penicillin, for the treatment of acute bacterial sinusitis and acute otitis media.³² Nevertheless, the use of cephalosporin antibiotics in patients with possible penicillin allergy requires careful consideration.

- **Carbapenems.** The members of the carbapenem group of antibiotics have an extremely broad spectrum of antimicrobial activity and are resistant to a variety of β -lactamases. Antimicrobial activity of carbapenem antibiotics is extremely high and the group is typified by imipenem and meropenem antibiotics. Both of these agents are administered parenterally. As carbapenem antibiotics are structurally related to penicillin, caution should be used when administering these agents to a penicillin-allergic patient. It has been reported that the incidence of carbapenem hypersensitivity among penicillin-allergic patients is 9–11%, which is similar to that reported for other β -lactam agents.^{34,35}
- **β -lactamase inhibitors.** β -lactamase inhibitors are substances that bind to β -lactamases and inactivate them. These inhibitors include clavulanic acid and sulbactam. β -lactamase inhibitors themselves have little direct antimicrobial activity, but when combined with an antibiotic, they extend the antibiotic's spectrum of activity and increase stability against β -lactamases.²⁶ Augmentin[®] is a product of amoxicillin combined with clavulanate, and Unasyn[®] is a combination of ampicillin and sulbactam. Although these antibiotics are not resistant to all types of β -lactamases, it has been demonstrated that they are effective against β -lactamase producing *Prevotella* strains involved in oral infections.³¹

Macrolides

Macrolide antibiotics have a common structure of a macrocyclic lactone ring to which are attached one or more deoxy sugars. Macrolide antibiotics are bacteriostatic agents that inhibit bacterial protein synthesis by binding reversibly to 50S ribosomal subunits of

sensitive microorganisms. Although the majority of bacteria involved in orofacial infections are susceptible to macrolide antibiotics, *in vitro* studies have demonstrated an increased prevalence of macrolide-resistant bacteria.^{36,37} Moreover, *Fusobacterium* species are highly resistant to macrolide antibiotics.^{37,38} On the other hand, the clinical response to macrolide antibiotics has generally been good and therefore these agents are often used for treatment of oral and maxillofacial infections. Erythromycin is the best known example of a macrolide, and clarithromycin and azithromycin are also available for treatment of orofacial bacterial infections.

Serious untoward effects are only rarely caused by erythromycin, although cholestatic hepatitis is the most striking side effect.²⁶ Other possible side-effects are hypersensitivity reactions, manifesting in the form of fever, eosinophilia, and skin eruptions. Macrolide antibiotics have a relatively high likelihood of drug interaction, because they are potent inhibitors of the cytochrome P450 system, which constitutes a complex set of drug-metabolizing enzymes.³⁹ Macrolide antibiotics have the potential to enhance the effects of various drugs (e.g. corticosteroids, carbamazepine, ciclosporin, digoxin, and warfarin).

As a unique pharmacokinetic property, azithromycin provides a much higher drug concentration in tissue (infection site) compared with the simultaneous serum concentration.⁴⁰ It has been suggested that fibroblasts serve as a reservoir of this drug in the tissue, permitting activity against the target organisms and possibly transferring antibiotic to phagocytes for activity against intracellular pathogens and delivery to infection sites.⁴¹ Azithromycin has an extremely long elimination half-life, which allows a large single dose to be administered, giving bacteriostatic levels in the infected tissue for several days.

Recently, the anti-inflammatory effects of 14-membered macrolides were discovered.⁴² An exploitation of this property involves a novel therapy, whereby a subantimicrobial dose of macrolide is used in the control of diffuse panbronchiolitis and management of chronic sinusitis in some countries.^{43,44}

Tetracyclines

The tetracyclines possess a wide range of antimicrobial activity against aerobic and anaerobic bacteria. The activity of these antibiotics is generally bacteriostatic by inhibition of bacterial protein synthesis through reversible binding to the 30S ribosomal subunit, thus blocking the interaction of aminoacyl-transfer ribonucleic acid with the ribosome.

Dairy products, antacids containing calcium, aluminium, zinc, magnesium or silicate, and vitamins with iron, can all interfere with the absorption of tetracyclines from the gastrointestinal tract when taken simultaneously with the drug.⁴⁵

Although gastrointestinal irritation, photosensitivity, hepatic toxicity, and renal toxicity are the notable side-effects, effects on teeth may, for

dentists, be the most recognizable side-effect caused by systemic administration of tetracyclines. Children receiving these agents may develop permanent brown discoloration of the teeth. If given to pregnant women, discoloration of the teeth may occur in their children. As a consequence, members of the tetracycline group should not be prescribed to pregnant women or children.

Interestingly, tetracycline antibiotics have non-antimicrobial properties including collagenase inhibition, anti-inflammatory actions, inhibition of bone resorption, and facilitating effect on fibroblastic growth.^{46,47} Some members of these agents are topically used as adjunctive treatment for periodontitis.

Clindamycin

Clindamycin binds exclusively to the 50S subunit of bacterial ribosomes and suppresses protein synthesis. Since clindamycin has excellent activity against viridians streptococci and strictly anaerobic bacteria, this agent is very useful in prevention and management of oral and maxillofacial infections. Clindamycin is well absorbed following oral administration and is widely distributed in many tissues including mandibular bones.⁴⁸

Clindamycin has sometimes been associated with causing diarrhea. The incidence of diarrhea following clindamycin treatment ranges from 2–20%.^{26,49,50} Pseudomembranous colitis is the most striking side-effect. This colitis is caused by the toxin from the organism *Clostridium difficile* that overgrows in the colon due to microbial substitution resulting from systemic antibiotic therapy.⁵¹ Pseudomembranous colitis is characterized by abdominal pain, diarrhea, fever, and mucus and blood in the stools, and can be severe, causing toxic megacolon, or even fatal. The incidence of this colitis following administration of clindamycin is reported to be 0.01–10%.^{26,52} Significantly, however, it has been reported that there is not a notable difference in the risk of the antibiotic-related colitis between clindamycin and β -lactam antibiotics.⁵² Skin rashes are reported to occur in approximately 10% of patients treated with clindamycin.²⁶

Aminoglycosides

Aminoglycosides are bactericidal inhibitors of protein synthesis, although the majority of bacterial protein synthesis inhibitors are bacteriostatic. These antibiotics include amikacin, gentamicin, kanamycin, streptomycin, and tobramycin. Aminoglycosides have a strong antimicrobial activity and are used primarily to treat infections caused by aerobic Gram-negative bacteria, including *Pseudomonas aeruginosa*, which tend to be resistant to multiple antibiotics. However, since the transport of aminoglycosides across the cytoplasmic membrane of bacteria is an oxygen-dependent active process, aminoglycosides have little activity against anaerobic bacteria because of the lack of the necessary transport system.^{7,26}

Aminoglycosides are relatively toxic compared with other classes of antibiotics. Nephrotoxicity and ototoxicity, that can involve both the auditory and vestibular functions of the eighth cranial nerve, are clinically notable and serious side-effects.

The quinolones

The older class of quinolones is of relatively minor interest now because of their limited antimicrobial spectrum and therapeutic use, and the rapid development of bacterial resistance. However, the introduction of fluorinate 4-quinolones has extended the antimicrobial activity and resulted in a particularly important therapeutic advance. The term quinolone is usually synonymous with fluoroquinolones.

Quinolones (fluoroquinolones) are bactericidal agents that inhibit bacterial DNA replication and transcription. As mentioned earlier, the quinolone antibiotics have an extremely broad antibacterial spectrum. These agents are well absorbed after oral administration and are widely distributed at various body sites.⁵³ The incidence of side-effects is relatively low. Nausea, abdominal discomfort, headache, and dizziness are the most common side-effects. Skin rashes including photosensitivity reactions can also occur. Arthralgias and joint damage can also develop in children receiving these agents.²⁶ Clinical use for prepubertal children and pregnant women should, therefore, be avoided. It has been reported that the risk of central nervous system side-effects, particularly convulsion, increases when receiving non-steroidal anti-inflammatory drugs (NSAIDs) during therapy with quinolones.⁵⁴ The relatively high cost of these agents may also limit clinical use in treatment of oral and maxillofacial infections.

Glycopeptides

A glycopeptide antibiotic is composed of glycosylated cyclic or polycyclic non-ribosomal peptides. Although several agents are currently available, vancomycin and teicoplanin are amongst the most important.

Glycopeptide antibiotics act primarily by inhibiting cell wall synthesis of Gram-positive bacteria, and this action is time-dependent. Vancomycin and teicoplanin exhibit strong antimicrobial activity against almost all types of Gram-positive organisms including methicillin-resistant *S. aureus*, although their spectra of activity are limited to Gram-positive organisms. This unique antimicrobial spectrum and also a level of high toxicity restrict the clinical use of glycopeptide antibiotics. Glycopeptide antibiotics are indicated for the treatment of serious, life-threatening infections by Gram-positive bacteria which are unresponsive to other less toxic antibiotics.

Glycopeptide antibiotics were historically regarded as the last effective line of defence. However, there are increasing reports of resistant enterococci strains.⁵⁵ Moreover, staphylococcal strains with high-level resistance to glycopeptides have increasingly been isolated from clinical specimens.⁵⁶

Nephrotoxicity is the most clinically important and serious adverse effect and its occurrence and severity are dependent on the dose. Therefore, measurement of the levels of the antibiotic in the plasma is required to monitor and reduce adverse events. Other possible adverse effects include anaphylaxis, toxic epidermal necrolysis, erythema multiforme, red man syndrome, super infection, neutropenia, leukopenia, thrombocytopenia, tinnitus, dizziness, and ototoxicity.

Metronidazole

Although metronidazole is used as an anti-protozoan agent, it is also available for the treatment of infections involving strictly anaerobic bacteria.²⁶ Metronidazole has a high antimicrobial activity against almost all of the strictly anaerobic bacteria, although this agent is not active against aerobes and facultative bacteria.⁵⁷ Therefore, metronidazole is effective for treatment of serious infections due to strict anaerobes. This agent is also a useful adjunct to antibiotics with an aerobic spectrum of activity (usually β -lactams and macrolide) in treatment of mixed aerobic (or facultative) and anaerobic infections or for empirical treatment of odontogenic infections.

Occurrences of serious side-effects are rare. The most common complications are headache, nausea, and metallic taste.²⁶ Vomiting, diarrhea, and abdominal distress occasionally occur. Metronidazole has a disulfiram-like effect, resulting in some patients experiencing abdominal distress, vomiting, flushing or headache if they drink alcohol during therapy. Patients should be cautioned against consuming alcohol during metronidazole treatment. There is conflicting evidence regarding possible teratogenic effects of metronidazole. The use of this agent during the first trimester of pregnancy should be avoided.

Antifungals

Antifungal agents are drugs that inhibit the growth of fungi. In contrast with bacteria, fungi are eukaryotic organisms and are therefore cytologically more similar to those of the host. As a consequence, there are limited numbers of drugs that affect fungal cells without a degree of toxicity to host cells. In general, more side-effects are likely to occur with antifungal agents compared with antibiotics.

Polyenes

Amphotericin B is the best known of the polyene antifungals. The mechanism of action of amphotericin B is fungal membrane disruption induced by the agent binding to a sterol moiety, primarily ergosterol, in the cell membrane of the fungi. Amphotericin B has a strong antifungal activity against a variety of fungal species. Absorption of amphotericin B from the gastrointestinal tract is negligible. Therefore intravenous administration of amphotericin B is employed in systemic therapy. The major acute reac-

tion to intravenous amphotericin B is fever and chills. Nephrotoxicity is another significant side-effect. Topical amphotericin B is a useful option for treatment of superficial candidosis and is considered safe.

Nystatin is another polyene antifungal agent that provides effective topical treatment of oral candidosis. It is usually administered in the form of oral suspension. Topical therapy with nystatin rarely causes side-effects.

Azoles

The azole agents are frequently used in the prevention and treatment of fungal infection because of their relatively broad antifungal spectrum of activity and lower toxicity compared with the polyene antifungals. These antifungals impair the synthesis of the fungal cell membrane by inhibition of sterol synthesis. The azole antifungals include two broad classes, imidazoles and triazoles. Miconazole is an imidazole agent that is widely used clinically, and fluconazole and itraconazole are triazoles. Although both classes share the same antifungal spectrum and mechanism of action, the systemic triazoles are more slowly metabolized and have lower toxicity to human cells compared with the imidazoles.

Fluconazole and itraconazole are administered systemically in the treatment of oral fungal infections. These agents are readily absorbed from the gastrointestinal tract. However, the absorption of itraconazole is greatly reduced in individuals who have reduced gastric acid production, so this agent should preferably be taken during or after meals.²⁶ Fluconazole and itraconazole are generally well tolerated. Gastrointestinal distress, nausea, vomiting, skin rash, and headache are major side-effects, but these can be managed with dose reduction. Importantly, these agents can interact with other systemically administered drugs. Miconazole is usually used topically which is considered safe, even during pregnancy.

Echinocandins

Echinocandins inhibit the synthesis of glucan (an important constituent of the fungal cell wall) and have a broad antifungal spectrum. Anidulafungin, caspofungin, and micafungin all belong to this group of antifungals. *Candida glabrata* and *Candida krusei*, which are not susceptible to the azole antifungals, are highly susceptible to echinocandins.⁵⁸ Serious side-effects occur rarely and adverse interactions with other drugs are less frequent compared with other types of antifungals.⁵⁹ Since all members of this class of agents are administered parenterally, echinocandins are mainly used for treatment of invasive fungal infections.

Flucytosine (5-fluorocytosine)

Flucytosine is transported into the fungal cell where it is deaminated to 5-fluorouracil (5-FU). 5-FU is further metabolized and then impairs the synthesis of

fungal DNA. 5-FU is also used as an anticancer agent, where it is administered in its active form because mammalian cells do not convert flucytosine to 5-FU. Although the antifungal spectrum of flucytosine is relatively narrow, this drug is active against *Candida* species. Flucytosine is well absorbed from the gastrointestinal tract, and widely distributed in the body.

Since flucytosine has similar properties to the 5-FU agents used in cancer treatment, flucytosine may depress the function of bone marrow and lead to the development of leukopenia and thrombocytopenia. This toxicity is thought to be the result of conversion of flucytosine to 5-FU by the microbial flora in the intestinal tract of the host.²⁶ Other side-effects including skin rash, nausea, vomiting, diarrhea, and severe enterocolitis have been noted. This agent is currently not often used in clinical practice in many countries.

Antiviral agents

Some viruses contain enzymes that initiate viral replication inside a host cell. As viruses have no metabolic machinery of their own, they use the enzymes of their host cell. Antiviral agents often inhibit virus-specific replicative events or preferentially inhibit "virus-directed" rather than "host cell-directed" nucleic acid or protein synthesis. Although various kinds of antiviral agents are currently available, the pharmacology of aciclovir is discussed in this section because the vast majority of viral infections in oral and maxillofacial regions involve members of the herpes virus group and aciclovir is the most commonly used antiviral agent in the treatment of herpes infection.

Aciclovir is an acyclic guanine nucleoside analog drug. Many generic forms of aciclovir are currently available. It is one of the most commonly used antiviral drugs and has been primarily used for the treatment of herpes simplex virus and varicella zoster infections. The mechanism of action of aciclovir is inhibition of viral DNA synthesis.

Aciclovir is generally well tolerated. Oral aciclovir has been associated infrequently with nausea, vomiting, diarrhea, rash, and headache, and very rarely with renal insufficiency or neurotoxicity. No increased frequency of abnormalities has been recognized in infants born to women exposed to aciclovir during pregnancy.²⁶ Intravenous aciclovir may cause renal insufficiency and, on rare occasions, central nervous system side-effects. Valaciclovir is an aciclovir pro-drug. It is converted *in vivo* to aciclovir.

Analgesics/antipyretics

Patients with infections often suffer from pain and fever. Paracetamol and NSAIDs are often used in control of these symptoms.

Non-steroidal anti-inflammatory drugs

NSAIDs are compounds that possess anti-inflammatory, analgesic, and antipyretic effects. Although

members of these classes of drugs are often heterogeneous and chemically unrelated, they nevertheless share certain therapeutic actions and side-effects.

Mechanisms of action

Most currently available NSAIDs inhibit both cyclooxygenase 1 (COX-1) and cyclooxygenase 2 (COX-2) activities. Cyclooxygenase is the enzyme responsible for the biosynthesis of prostaglandins, which are closely associated with the development of inflammation and certain autacoids. Therefore, inhibition of this enzyme is thought to be a major mechanism of NSAIDs' activity. COX-1 is a constitutive isoform found in blood vessels, stomach, and kidney, whilst COX-2 is induced at sites of inflammation by cytokines and inflammatory mediators. The inhibition of COX-2 is thought to mediate, in part, the anti-inflammatory, analgesic, and antipyretic actions of NSAIDs. However, the simultaneous inhibition of COX-1 results in unwanted side-effects, in particular induction of gastric ulcers, which result from decreased prostaglandin and thromboxane formation.

Classification

Table 29.8 provides a classification of NSAIDs and other analgesic and antipyretic agents based on chemical categories. Although individual agents inhibit cyclooxygenase by differing mechanisms, agents that have similar chemical properties generally share certain therapeutic properties and side-effects.

Shared therapeutic activities

All NSAIDs are antipyretic, analgesic and anti-inflammatory, but there is an important difference in their activities. NSAIDs do not change the perception of sensory modalities other than pain. Postoperative

Table 29.8 Classification of non-steroidal analgesics.

Group	Analgesics
Salicylates	Aspirin
Para-aminophenol derivative	Paracetamol
Acetic acid derivatives	Indomethacin
	Sulindac
	Etodolac
	Femansates
	Tolmetin
	Ketorolac
	Diclofenac
Propionic acid derivatives	Meclofenamate
	Ibuprofen
	Naproxen
	Fenoprofen
	Ketoprofen
	Flurbiprofen
	Oxaprozin
Enolic acid derivatives	Piroxicam
	Meloxicam
	Nabumetone
COX-2 selective inhibitors	Celecoxib
	Valdecoxib

pain or pain arising from inflammation can be controlled by NSAIDs. NSAIDs reduce the body temperature in febrile state but do not affect normal body temperature in the absence of fever.

Side-effects

The clinically important side-effects that are shared by NSAIDs are generally dose-dependent.

- *Gastrointestinal tract.* Irritation of the gastrointestinal tract is the most common side-effect. Complications include epigastric distress, stomach pain, nausea, vomiting, dyspepsia, gastric ulceration, and gastrointestinal bleeding. Gastric ulceration is sometimes severe and can be accompanied by anemia from the resultant blood loss. It should be remembered that gastrointestinal side-effects are sometimes painless, although they can result in admission to hospital, surgery, and possibly death. The risk factors include advanced age (especially >65 years old), previous peptic ulcers or ulcer complications, concomitant use of glucocorticoids or anticoagulants, and high-dose or prolonged NSAID administration.^{60,61}
- *Blood.* Ingestion of NSAIDs prolongs the duration of bleeding due to a blockade of platelet aggregation. Through exploitation of this effect, aspirin can be a useful agent in the management of arterial thrombosis and prevention of adverse cardiovascular events.
- *Kidney.* NSAIDs may change renal blood flow and ultimately may cause renal impairment, which leads to retention of salt and fluid and resulting hypertension. The risk of renal impairment may increase in instances where NSAIDs are used in combination with other nephrotoxic agents or under some medical conditions such as chronic renal diseases and congestive heart failure.
- *Influence on pregnant women.* Similar to other drugs, there is a concern over possible teratogenic effects of NSAIDs. Moreover, NSAIDs may cause premature closure of the fetal ductus arteriosus and renal impairments in the fetus.⁶² Consequently, use of NSAIDs is not recommended during pregnancy, particularly during the first and third trimesters.
- *Liver.* Epidemiological evidence indicates that the use of salicylates and some members of NSAIDs are associated with the occurrence of severe hepatic injury and encephalopathy observed in Reye's syndrome.^{63,64} This syndrome is rare, but is often fatal, especially when associated with infection with varicella zoster virus and various other viruses, e.g. influenza viruses. The use of these agents in children or adolescents with chickenpox or influenza is contraindicated, but paracetamol may be a useful alternative.
- *NSAID intolerance.* The prevalence of intolerance for aspirin and most NSAIDs is 5–6%.⁶⁵ NSAID intolerance manifests as asthmatic attacks or urticaria/angioedema. Asthmatic attacks are often

severe and life-threatening. Although rare in children, up to 20% of the asthmatic population is sensitive to aspirin and other NSAIDs.⁶⁵ Patients who have, or have ever had asthma, frequent incidences of “stuffed” or “runny” noses, or nasal polyps, have a higher risk of hypersensitive attack following use of NSAIDs.

Paracetamol (acetaminophen)

Paracetamol has similar analgesic and antipyretic effects to NSAIDs. However, its anti-inflammatory effects are very weak. The mechanism by which paracetamol reduces fever and pain remains unclear. Since its mechanism of action differs from those of other NSAIDs, paracetamol lacks certain side-effects exhibited by other NSAIDs, such as gastrointestinal tract damage and blockade of platelet aggregation. Although paracetamol is regarded as safe and well tolerated during pregnancy, it should be noted that acute overdosage can cause fatal hepatic damage.

Principles of diagnosis of oral and maxillofacial infections

All patients are evaluated based on careful collection of history, physical examination, results of laboratory tests, and imaging studies. Infections, especially bacterial infections, can cause life-threatening complications. Therefore the emergency level must be evaluated initially.

Assessment of emergency level

The consciousness level and airway status of the patient are first determined. If any indication of significant complication or suspected serious condition is evident, the patient must be referred to an emergency clinic or specialist immediately following checking the vital signs.

Recording of medical history

Once the patient has been confirmed as not requiring critical care, an infection history is obtained by interview or self-administrated questionnaire. The patient's primary complaint and history of the present infection are carefully obtained. Necessary information includes the onset, nature, location, and duration of each symptom, history of recurrence, including its frequency, and responses to previous treatment.

A medical history of the patient between birth and the time of assessment is necessary for adequate diagnosis and management. Information on any medication previously prescribed must be fully obtained. The patient's defense level must be assessed together with the medical information. Common immunocompromising factors are listed in Table 29.9. Although any component of the host defense system can be suppressed, the majority of listed factors com-

Table 29.9 Immunocompromising factors associated with increased occurrence and poor prognosis of oral and maxillofacial infections.

Diabetes mellitus
Systemic use of corticosteroids
Systemic use of immunosuppressants
Malignant tumors
Leukemia, lymphoma, myeloma
Antineoplastic chemotherapy
Radiation therapy
Alcoholism
Cirrhosis
Chronic renal failure
Splenectomy
Organ transplantation
Collagen vascular disease
HIV/AIDS
Malnutrition

promise the functions and production of phagocytes and cytokines. Assessment of the hydration and nutritional status of the patient is also important. Patients may not take in sufficient water and food because of pain, poor appetite, trismus, and difficulty with chewing and swallowing. Furthermore, fever also increases fluid loss and calorific needs. As a consequence, a degree of dehydration and malnutrition may occur. The patient's fluid balance and nutrition level can often be anticipated through interview, although actual status should be evaluated based on blood and urine tests.

The experience and details of previous hypersensitive reactions and suspected side-effects of medications must be recorded.

It should be noted that patients often have undiagnosed diseases (especially diabetes, chronic hepatitis, infection with a hepatitis virus, HIV, and tubercle bacillus carriage), or in the case of some women, be unaware of a pregnancy. As a result, information obtained from interview may not be completely reliable.

Assessment of the patient's present status

Recording of symptoms

All symptoms of the patient must be determined. The nature, location, and duration of pain have to be recorded. Likely symptoms may include headache, chills, sweating, loss of appetite, and insomnia. Any difficulty in swallowing, breathing, eating, chewing, and opening of the mouth must be recorded to evaluate oral dysfunction.

Infections in the maxilla might involve the maxillary sinus. Rhinorrhea, epistaxis, problems breathing through the nose, nasal congestion, and changes in

sense of smell indicate possible sinusitis. In the case of the mandible, an abnormality of sensation in the area innervated by the mandibular nerve would suggest a significant inflammation of the bone marrow.

Physical examination

Physical examination includes assessment of the patient's general condition and also incorporates a comprehensive regional examination.

The general appearance of the patient, especially whether or not they have an appearance of fatigue, feverishness or malaise (so-called '*toxic appearance*') and the skin colour of the face needs to be inspected.

Vital signs must also be checked. These include the respiratory rate, pulse rate, blood pressure, and body temperature. Normally, the respiratory rate of healthy individuals is 14–16 breaths per minute, but it may increase as infection progresses. A decrease in blood oxygen level detected by pulse oximetry might indicate a possible airway obstruction. Pulse rate may also increase as the body temperature rises. In severe infection, the pulse rate often exceeds 100 beats per minute. Although infection itself has little effect on blood pressure, significant pain and anxiety might indirectly elevate blood pressure, whilst dehydration and shock may cause a reduction in blood pressure. Fever is often evident even in mild infection. It should be noted that various non-pathogenic factors affect body temperature. Fevers in children tend to be exaggerated, whereas elderly patients may experience little temperature change, even in severe infection. It is important to appreciate that non-infective diseases (e.g. collagen disease, cancer) can also induce fever, so it is essential to determine initially whether a fever actually involves an oral infection.

Regional examination starts with checking the symmetry of face. The area and nature of swellings, erythema, warmth, and tenderness are examined by careful observation and palpation. If the swelling is subtle, the clinician should ask the patient to describe any areas of swelling that they are aware of. The nature of the swelling varies from feeling very soft and almost normal through to a firmer or hard swelling, not dissimilar to a tightened muscle. Swelling due to the accumulation of pus has a different feel to it from that due to edema, and the former is described as fluctuant. Fluctuance has the feeling of a fluid-filled balloon, and can be determined by placing the fingers at the sides of the swelling and detecting fluid movement (Fig. 29.8). In the case of a deep-seated abscess, however, detection of fluctuance may be difficult by palpation.

Regional lymph nodes, and especially the submandibular and submental lymph nodes, should be inspected for enlargement, tenderness, redness, and warmth of overlying skin.

Dental and periodontal status is recorded together with any local inflammatory signs. If infection is suspected as being of dental origin, the probable source

Fig. 29.8 Fluctuance. As one finger applies pressure, another detects the fluid movement.

of infection should be determined in the oral examination (e.g. inspection, palpation, and percussion). The maximum vertical range of jaw motion is recorded for determining the degree of trismus.

Imaging studies

Radiographic examinations are important in determining the possible cause of infection and the extent and status of the lesion. The clinician must be aware of the normal radiographic anatomic structures. An overview of infection-related radiographic methods is presented here. For a more detailed overview see Chapter 2.

Plain films

Radiographic examinations often start with a plain film study. Standard dental (intraoral) X-ray film, especially for a periapical radiograph, is suitable for examining localized dental and alveolar diseases because of its fine and clear image quality, cost-effectiveness, and low radiation exposure. As a panoramic radiograph (pantomogram) takes a much wider area of image than intraoral films, it is particularly useful for making a precise localization of infection and to demonstrate the extent of infection and any anatomic relationship between the lesion and surrounding structures. This approach is also available for the patients with trismus or other extenuating conditions, such as severe gag reflex caused by placement of film inside the mouth. The individual structures are somewhat unclear and fine detail cannot be seen, since the panoramic film provides a lower resolution picture than that obtained with the intraoral films.

A Waters' projection and posterior-anterior view may demonstrate inflammation within paranasal sinuses.

Computed tomography and magnetic resonance imaging

Computed tomography (CT) is available in medical imaging to supplement radiographs and medical ultrasonography. CT is particularly useful in examining fascial space infections, osteomyelitis of the jaw, and paranasal sinusitis. The high cost, possible side-effects of iodinated contrast agents (allergic reaction and kidney damage), and the relatively high radiation exposure are limitations of CT. Imaging artefacts, especially those caused by metallic materials (e.g. crown and reconstruction plate) may also reduce the effectiveness of CT.

Magnetic resonance imaging (MRI) is available for examining a variety of infections. An MRI study is more sensitive for the diagnosis of some types of infections, such as osteomyelitis of the jaw and suppurative arthritis of the temporomandibular joint, compared with CT scans. However, the cost of MRI examinations is generally higher than that of CT. Artefacts related to the use of metallic instructions may also disturb the MRI study. Use of MRI should be avoided in patients who have implanted medical devices that are strongly affected by magnetism, as evident with artificial heart pacemakers.

Radionuclide scans

A radionuclide scan is a way of imaging parts of the body by using a small dose of a radioactive chemical. A tiny amount of radionuclide, which is a chemical that emits gamma rays, is introduced into the body, usually by an injection into a vein. The radionuclide tends to collect or concentrate in specific organs and tissues with certain pathogenic conditions, including inflammation. The gamma rays that are emitted from inside the body are detected by a gamma camera and are converted into an electrical signal and subsequently the computer builds a picture. There are different types of radionuclides, and the radionuclide employed depends on which part of the body is to be scanned. Although radionuclide scanning may be unnecessary in making diagnosis of most forms of infection in the oral and maxillofacial region, it is a particularly useful imaging technique for the diagnosis of acute osteomyelitis (see the later section, Osteomyelitis of the jaw).

Blood and urine tests

Results of blood and urine tests can provide significant information relating to infection. The data are available not only for diagnostic purposes but also in the assessment of the patient's general condition and evaluation of the response of treatment through data monitoring.

Systemic effects of infection may result in the abnormal fluctuation of various factors measured by a blood test. Certain data are closely associated with progression of infection. These include leukocyte count and differential C-reactive protein (CRP) level, and erythrocyte sedimentation rate (ESR).

Leukocyte count and the leukocyte differential

Although the normal leukocyte count in peripheral blood ranges between 4000 and 11 000 cells/ml,³ it generally increases during the active phase of microbial infections (leukocytosis). In addition, the percentage of neutrophils in the blood may also be elevated. In the case of severe infection, immature neutrophils are often evident (this is referred to as a left shift). After the infection has reached its peak, the leukocyte count and the percentage of neutrophils will gradually decline to their normal range. Therefore the stage of infection can be determined by monitoring the fluctuation of these factors.

C-reactive protein

The CRP level in peripheral blood is frequently measured in the assessment of the activity of infection. The CRP value can reflect the intensity of inflammation with greater sensitivity than other blood factors including leukocyte count. However, the range of CRP fluctuation varies between patients. The monitoring of CRP level in the same patient is extremely useful in evaluating the outcome of therapy.

Erythrocyte sedimentation rate

An elevated ESR indicates the presence and intensity of infection. However, the normal ESR range can vary with age, ethnicity, gender, and with certain underlying diseases.²¹ Moreover, it reacts slowly to changes of inflammatory activity. The sensitivity and specificity of ESR on diagnostic usage for infection is not high.

Other tests

Blood and urine tests may also demonstrate anemia and abnormalities of hepatic and renal function, fluid balance, and nutrition level. Moreover, urinalysis and/or a blood sugar test may detect previously undiagnosed diabetes. It should be noted that severe infection itself tends to raise the blood sugar level, and any recent use of corticosteroids, alcohol or drug abuse or consumption of food and drink containing glucose may affect the data.

Microbiologic examination

The purpose of microbiologic examination is to identify any causative microorganisms and to determine

their susceptibility to antibiotics or antifungals. Microbiological examination is of great value for clinical practice because case-specific antimicrobial regimens can be made based on the results. However, data obtained from improper sample collection, poor technique, and inappropriate transport and management of specimen may prove misleading (Table 29.10).

Microbial examination generally comprises a microscopic analysis of the specimen and its subsequent culture. Culture is necessary for identification of organisms and any subsequent susceptibility testing (Fig. 29.9). Aerobic and facultative bacteria and fungi may grow relatively rapidly on agar media, whilst sufficient growth of strictly anaerobic organisms requires at least a few days. Therefore microbiologic examination, particularly involving the culture of anaerobic organisms, usually takes several days.

When collecting specimens, the clinician should record the site of sampling, visual features (for example, the presence of any yellow thick, blood-like or thin liquids), the odor of the specimen, and status of the abscess (e.g. whether it has already drained). A rotten or gangrene-like odor of the specimen indicates an involvement of anaerobes.

Large numbers of microorganisms reside in the human body, especially within the mouth. Therefore specimens may often be contaminated with indigenous microorganisms that are not involved in the infection. To minimize this risk, the material should be taken from sites that are representative of the infection, and any contact with surrounding tissues

Table 29.10 Summary of specimen collection guidelines for microbiologic examination.

Avoid contamination from indigenous flora
Aspiration is preferred to swab for sample collection
Collect a sample from correct site by proper technique
Collect adequate volumes
Place the specimen in adequate container or transport medium
Send the specimen to laboratory as soon as possible
Do not hesitate to re-examine if unreasonable results are obtained

Fig. 29.9 (a) Picture of an agar plate for antimicrobial susceptibility. A wide area of no bacterial growth around antibiotic disks is evident, suggesting that the strain is susceptible to the antibiotic. (b) E-test provides the minimal inhibitory concentration of an antibiotic.

and fluids during collection must be avoided. Pus obtained by aspiration is less likely to be contaminated, whilst sampling with swabs tends to result in a high likelihood of contamination. However, pus specimens from abscesses that have already been opened are likely to be contaminated even when sampled by aspiration.

Some microorganisms are sensitive to *in vitro* environments. For example, oxygen kills strictly anaerobic microorganisms and drying kills most bacteria when left exposed to the air. Conversely, some types of aerobic organisms can multiply when stored for several hours at room temperature. Therefore, inadequate management of specimens after collection and delayed transport to the laboratory may result in deterioration and overgrowth of microorganisms within specimens and may produce incorrect results. An insufficient sample volume may also provide inaccurate results.

Purulent infection of dental origin usually involves strictly anaerobic bacteria. Aspiration is recommended for sampling because of the likely collection of a sufficient amount of material and the reduced risk of exposure to oxygen. The optimal time for specimen transport to the laboratory is 2 hours or less if an adequate volume of material is obtained; however if only small volumes of material are sampled, then the specimen should be processed within 15–30 minutes of collection.⁹ These processing times may be achievable when the diagnostic microbiology laboratory is located in close proximity to the clinic. However, if laboratory facilities are not locally available, specimens need to be stored under adequate transport conditions suitable for the suspected microorganisms (Fig. 29.10), and sent to an appropriate laboratory within 24 hours. In the case of swabs, the specimen must be kept in an appropriate transport medium and immediately sent to the microbiology laboratory.

Pieces of infected soft tissue or bone obtained surgically can also provide suitable specimens for microbiologic analysis. Such material should be placed in sterile Petri dishes or screw-top bottles with a small

Fig. 29.10 Pus specimen obtained by aspiration (a) should be held in an anaerobic transporter (b), which contains a substance that eliminates oxygen. Swab sample (c) must be handled to avoid drying and sent to the laboratory immediately.

volume of saline solution to prevent desiccation and again must be transported to the laboratory as soon as possible.

A positive blood culture demonstrates that an infection is spreading through the bloodstream. Blood culture is important to determine if sepsis is occurring in the patient. It is also an option for assessing microbial flora involved in orofacial infection if an adequate pus specimen is not available. A minimum of 10 ml of blood is collected through venipuncture and inoculated into blood bottles (Fig. 29.11), which contain specific culture media in accordance with the suspected microorganisms present.

It is sometimes difficult to interpret microbiologic results. Blood-like or thin pus often yields extremely low bacterial counts compared with thick, yellow pus, and the former is therefore likely to produce less accurate results. Sampling pus in the central part of the abscess, where bacteria might have lost their viability, may also be a cause of false-negative culture. In patients receiving systemic antibiotics, the pus or blood (in the case of blood culture) may also contain traces of antibiotic. As a consequence, culture results may often be incorrect due to the selection of certain organisms by the antibiotic. In such circumstances the clinician should not hesitate in retesting the sample site.

Principles of management of bacterial infections

This section specifically focuses on the principles of management of bacterial infection, with fungal and viral infections reviewed independently (see later sections, Oral fungal infections and Oral and perioral viral infections). The management of bacterial infection consists primarily of surgery, antimicrobial therapy, and medical supportive care, with the exception of emergency treatment.

Fig. 29.11 Blood culture bottles. Left bottle is for aerobic culture and right one contains culture medium for strict anaerobes.

Surgical treatment

Surgery is an essential part of the treatment of suppurative infections. It ranges from simple and relatively non-invasive procedures, such as pulpectomy and tooth extraction, to wide incision of abscesses in the head and neck. Surgery may facilitate the removal of the cause of infection and promote an improvement of the host defense through elimination of accumulated pus, debris, and necrotic tissues. Surgical drainage may obviate the use of antibiotics or may enhance the effectiveness of antibiotics through restoring vascular flow at the infection site.

Drainage by incision

In the case of pus-producing infections, incision of the abscess cavity and subsequent drainage of pus are critical to the resolution of infection. Pus contains dead leukocytes (neutrophils) together with the causative bacteria. An adequate drainage of pus also provides a reduction in tissue tension, improvement of the local blood supply, and change in the local environment (increased oxygenation of the infected area). Even if antibiotics are administered, failure of drainage may result in further progression of infec-

tion and may delay resolution. Clinicians should carefully palpate swollen areas to detect fluctuance, which indicates abscess formation. Any abscess should be incised, even if other surgical procedures including tooth extraction and endodontic therapy are undertaken.

The standard process of incision and drainage is presented in Fig. 29.12. The notable principles are as follows:

- *Optimal timing.* The optimal timing of incision varies. In general, abscesses should be incised when pus has accumulated within the cavity. Most infections start as a phase of cellulitis that may occur as a soft, doughy, and diffuse swelling. In this stage, limited amounts of pus are available, and infection may not respond to surgery. However, in cases of cellulitis that spread widely, especially fascial space infections, an early incision may be recommended because undetected abscesses may appear through incision and subsequent exploration, and the surgical procedure may provide a reduction of pressure in the area of cellulitis.
- *Anesthesia.* Conventional local infiltration anesthesia may be satisfactory for incision of superficially placed and well localized abscesses. The anesthetic

Fig. 29.12 General process of incision and drainage for oral abscess. (a) Blade of the scalpel is inserted parallel to the gingival margin. (b) A hemostat is inserted through the incision into the abscess cavity, and the beaks of the hemostat are spread gently to open the cavity when encountering the abscess cavity and removed open to avoid catching vital structures. (c) A drain is inserted and sutured with surrounding mucosa.

is injected into the gingiva, mucosa or skin surrounding the abscess, but should not be injected directly into the abscess cavity. Since inflammation creates an acidic environment, local anesthetics may be slower than normal in their onset of action and less effective in inflamed tissues.⁶⁶ Therefore, a greater volume of anesthetic is often required to be administered to achieve adequate anesthesia compared with that used in routine dental treatment. Infiltration anesthesia may be inadequate in cases of extensively spreading or intensive infection. Use of inferior alveolar nerve block, sedation or general anesthesia should be considered.

- *Aspiration of pus prior to incision.* Aspiration of pus from the abscess cavity using a disposable sterile syringe with a large-gauge needle (usually 18 gauge) prior to actual incision of the abscess is recommended for the following reasons: (1) actual pus accumulation can be confirmed; (2) the procedure may provide clues as to the precise localization of the abscess; and (3) pus obtained by aspiration is more suitable for bacteriologic examination. The authors recommend the use of a small-volume syringe (2 ml), because aspiration using a large syringe often causes pain through the strong suction pressure. The surface of the mucosa or skin must be disinfected with an appropriate antiseptic (for example, povidone-iodine and ethanol) before aspiration to avoid contamination of the specimen.
- *Avoid damage to important structures.* An incision must be carefully placed to avoid any damage to important structures, such as salivary gland ducts and nerves (especially the facial nerve branches).

The incision should be made in a direction parallel to the branch of facial nerves near the infection site. As the marginal mandibular branch of the facial nerve dips below the lower border of the mandible, an incision line is recommended to be at least two fingers' width below the lower border (Fig. 29.13). Attention is also required to avoid injury of the mental nerve by incision of the abscess in the region of the mandibular premolars. As damage to the greater palatine artery and lingual artery may result in significant hemorrhaging, incision of palatal and pharyngeal abscesses and surgical drainage of sublingual spaces need to be performed carefully.

- *Incision in a cosmetically or functionally acceptable place.* Although an intraoral incision generally does not cause serious cosmetic problems, the incision should not be longer than necessary. Careless incision might result in a later functional problem. Incision at sites related to oral function, such as the frenums should be avoided. In the case of extraoral incision, the incision should be placed in an esthetically acceptable area, for example, in the shadow of the jaw, beyond the hairline, and parallel to the lines of skin tension.
- *Incision with deliberation to maximize efficient drainage.* An incision at a position that encourages drainage by gravity will obviously be desirable.
- *Use of blunt dissection.* A superficially placed abscess cavity may be opened easily by incision. Vestibular abscesses usually form between the bone surface and the periosteum. In these cases, the scalpel blade is inserted to the surface of the cortical plate in order to open the abscess beneath the periosteum. If pus does not discharge, the inci-

Fig. 29.13 An incision at submandibular region or mandibular angle should be placed two fingers' breadth below the lower border to avoid injury of the marginal mandibular branch of the facial nerve.

sion may not be deep enough. In the case of deeply placed abscesses, careless incision might cause serious damage and injury to vital structures, especially veins and nerves. A scalpel must not be inserted into deep tissues. Once the skin or mucous membrane is incised, the abscess must be approached by blunt dissection using a hemostat, as blunt dissection should minimize the risk of significant injury within tissues. A closed hemostat is inserted through the incision into the abscess cavity. Once the abscess cavity is encountered the beaks of the hemostat are spread to break up any small loculations or cavities of pus that have not been opened by the initial incision; this is done in a direction parallel to the vital structures in the region. The beaks of the hemostat should not be closed within the tissues, in case a vital structure is damaged.

- *Irrigation of the abscess cavity.* In the case of large abscesses, irrigation with saline may be effective in reducing residual contamination.
- *Placement of drain.* Abscesses tend to seal off shortly after incision. Therefore, a drain may be inserted to maintain the opening of the abscess cavity to encourage drainage of pus that is residual or forming. In the case of small abscesses the placement of

a drain may not always be required. A sterile Penrose drain (Fig. 29.14) is commonly used for intraoral abscess drainage. A drain of adequate length to allow drainage from the depth of abscess cavity is inserted using a hemostat, and it is then fixed by a suture to surrounding tissues that are not necrotic, to prevent unwanted movement and loss of the drain. The wound must not be closed.

- *Removal of the drain.* Drains should be removed when the drainage ceases or becomes minimal. Prolonged placement of drains might delay the normal wound healing process. Drains may be shortened over the next few days to ensure that drainage is completed.

Endodontic therapy (root canal opening)

The majority of orofacial bacterial infections are endodontic in origin. Drainage through the root canal is effective (Fig. 29.15), although infections of non-periapical origin will not respond to this procedure. Despite the fact that the extent of this drainage is usually smaller than that of an incision, it does contribute to prevention of further progression and may allow resolution of infection. Pus commonly accumulates in abscess cavities at the tip of the causative root apex, on the inside of the alveolar bone. Therefore, surgical opening of the root canal may be considered even in instances of cellulitis, in which a palpable abscess has yet to form. However, if the tooth has been restored

Fig. 29.14 A Penrose drain.

Fig. 29.15 The procedure of endodontic drainage. (a, b) An endodontic reamer is inserted as far as the abscess cavity at the tip of root apex. (c) Pus may be drained through the opened root canal.

with a post crown or if a root canal has been closed or constricted due to calcification or previous endodontic treatment, endodontic drainage may be very difficult. Severe root canal curvatures may compromise root canal treatment. Severe trismus also limits the application of endodontic drainage.

Although the actual effect is controversial, trephination techniques can be employed in cases of periapical abscess where there is extensive pain, when there is no swelling, and/or drainage through conventional endodontic therapy is not feasible (Fig. 29.16).

Tooth extraction

Extraction of teeth involved in infection results not only in the removal of the cause but also drainage of accumulated pus through the socket. Early tooth extraction is generally recommended, although it might cause additional swelling. A loose tooth often causes pain caused by contact with opposite teeth, food, tongue, and lip during chewing and swallowing, and therefore should be removed as soon as possible. It should be noted that the offending tooth is sometimes able to be salvaged by adequate dental treatment after resolution of the acute infection. Mild infections therefore do not always require tooth removal.

Surgical removal of foreign bodies involved in infection

As with tooth extraction, surgical removal of any infected foreign bodies aims to remove the cause of infection, eliminate harmful stimuli, and encourage drainage. Loose implants, screws, plates, and other materials should be removed as soon as possible.

Fig. 29.16 Trephination involves artificial penetration into the abscess cavity, which is made through the mucosa and cortical plate to make a pathway for drainage.

Inappropriate surgical procedures

In some Middle Eastern countries, application of hot metal instruments (Wassam) by non-medical “doctors” has been used in an attempt to relieve the pain of dental infections. This totally inappropriate approach results in acute superficial skin infection and extensive ulceration that heals with scarring (Fig. 29.17).

Antimicrobial therapy

Prevalence of antibiotic-resistant organisms

Systemic antibiotic therapy is undoubtedly a significant part of the management of bacterial infections. However, recent years have seen a dramatic increase in the prevalence of antibiotic-resistant organisms and emergence of multidrug-resistant bacteria. Bacteria may become resistant to antibiotics through continued exposure to an antibiotic, and in the case of systemic antibiotic therapy, resistant bacteria at other body sites might develop. It is of great concern that many clinicians still use antibiotics inadequately, with poor understanding of the consequences.^{67–69} Antibiotics are an essential weapon in the combat of bacterial infections and are the result of a great deal of research and development over many years at a significant financial cost. Proper use of antibiotics is therefore an ethical duty for all clinicians.

The role of antibiotic therapy

Undoubtedly, antibiotics are overprescribed in clinical practices of dentists and oral surgeons. It is critical to keep in mind that the priority in the management of oral and maxillofacial infections is to improve host defenses through surgical procedures. Even if more enhanced and improved antibiotics are developed, this principle will not change. In circumstances where drainage is unavailable (for example in the case of

Fig. 29.17 A patient with a superficial skin infection of the face caused through intentional burning with application of a hot iron to an area of the face that was swollen due to an odontogenic infection (this “procedure” is referred to as Wassam).

cellulitis), the role of antibiotics is important. However, the role of systemic antibiotic therapy is as an adjunct to surgery, and the prime purpose of such therapy is to prevent spread of infection and onset of serious complications.

Clinicians must recognize the potential negative effects of any antibiotic therapy. All antibiotics may induce a variety of side-effects or interact with other systemically administered medicines, and some of these effects are potentially serious and fatal. Antibiotics distribute throughout the body, and may disrupt microbial homeostasis at a variety of body sites, with resulting clinical problems including diarrhea and mucosal candidosis.⁷⁰ Obviously, broad-spectrum antibiotics are more likely to disrupt such microbial homeostasis. As described earlier, antibiotic therapy increases the chances of the occurrence of bacterial resistance. The cost of the antibiotic might also be an important matter for consideration.

Indications for antibiotic use

Indications for antibiotic therapy are presented in Table 29.11. Systemic antibiotics may be unnecessary to treat a minor, chronic or well localized abscess. Management of dry socket, mild acute infection, and chronic infection do not require antibiotic treatment. However, in immunocompromised patients, use of systemic antibiotics may be advocated even if the infection is not severe.

Table 29.11 Indications and non-indications for systemic antibiotic therapy.

Situation in which antibiotic therapy is necessary or recommended

Acute orofacial suppurative infections
Osteomyelitis
Acute maxillary sinusitis
Suspected actinomycosis
Acute necrotizing ulcerative gingivitis
Acute bacterial infection in an immunocompromised patient
Fascial space infections
Acute peritonsillar abscess
Acute traumatic and surgical wound infections

Situation in which antibiotic therapy may be unnecessary

Pulpitis
Chronic periapical abscess or disease
Gingivitis and periodontitis
Minor vestibular abscess
Chronic or mild acute pericoronitis
Peri-implantitis
Postoperative swelling and pain
Alveolar osteitis (dry socket)
Chronic wound infection
Fungal or viral infection

Table 29.12 Conditions where microbiologic examination is recommended. Microbiologic examination includes identification of microbes by culture and antibiotic susceptibility testing.

Severe infections including fascial space infections
Rapidly spreading infection
Infection that exhibits little or no response to the present therapy
Recurrent infection
Possible infection of non-oral origin
Osteomyelitis
Maxillary sinusitis
Suspected actinomycosis
Surgical wound or trauma infection
Infection in immunocompromised patients

Empiric therapy and the necessity of microbiologic examination

The choice of antibiotic therapy should ideally be based on laboratory data. However, such results are often not available for several days. The cost of examination also limits such an approach in routine practice.

Orofacial bacterial infections, especially odontogenic infections, are most often caused by predictable organisms. As a consequence, routine microbiologic tests are not necessary and the initial choice of antibiotic is largely done on an empiric basis. However, there are circumstances where laboratory tests are strongly recommended. These include severe cases, rapidly spreading infection, and infection in immunocompromised patients (Table 29.12). Microbiologic examination is of great value when treating osteomyelitis, sinusitis, suspected actinomycosis, surgical site infections (surgical wound infections), and traumatic wound infections because of the uncommon organisms that might be involved.

Principles of antibiotic choice

Empiric choice of an antibiotic is based on the following principles (Table 29.13):

- *Predicted microbial flora involved in the infection.* Most orofacial infections involve predictable organisms. Clinicians should therefore have contemporary knowledge of the microbiology of orofacial infections.
- *Choice of the specificity and spectrum of the antibiotic.* Ideally, antibiotics will target only the causative organisms without an effect on the other commensal microbes. Often the most suitable candidate antibiotics are those of the penicillin class. Antibiotics that exhibit a broader antimicrobial spectrum should be reserved for situations where narrower-spectrum alternative antibiotics are unsuitable.
- *Use of a regimen with a single antibiotic.* Use of two or more antibiotics in combination may be

Table 29.13 The principles of empiric antibiotic therapy.

Understand the role of antibiotic therapy and indication of antibiotic use
Predict microbial flora involved in infection
Choose antibiotic with adequate spectra for predicted microbes
Generally single antibiotic use
Use an antibiotic with low toxicity and a reduced likelihood of side-effects
Choose antibiotic in accordance with patient's physical condition
Bactericidal antibiotic is recommended if the patient's immunity is impaired
Consider cost of antibiotic therapy

advantageous in certain clinical situations, providing a synergistic activity against specific organisms or enhancement of antibacterial spectrum. Therefore, a multidrug regimen of antibiotics is advocated for management of patients with severe infection or a high likelihood of a serious complication. However, this kind of regimen may increase the possibility of disrupted microbial homeostasis. Moreover, antagonistic antimicrobial effects can occur depending on the combination and the bacteria. A multidrug regimen of antibiotics is generally more expensive compared with that of a single antibiotic. Most infections can be treated with a single antibiotic, thereby reserving the multidrug regimen as a later option if required.

- *Use of safe antibiotics.* Although all antibiotics have various degrees of toxicity and a range of side-effects, β -lactam antibiotics, especially penicillins, are generally considered safe. Macrolides have a low incidence of side-effects, and quinolones (fluoroquinolone) and metronidazole have minor toxicity. In contrast, aminoglycosides and vancomycin exhibit high renal toxicity. Antibiotics may provide an undesirable enhancement or reduction of the effect of medicines that are administered systemically, such as anticoagulants, theophylline (drug for respiratory diseases), and the birth control pill. In particular, macrolides are more likely to cause such interactions.
- *Consideration of the patient's condition.* The systemic use of antibiotics in pregnant women involves an evaluation of risk versus benefit. Penicillin may be the most suitable candidate in pregnancy and for infants and children in the tooth- and skeletal-development stages. Cephalosporins, erythromycin, and clindamycin may be acceptable alternatives, whilst clinical use of tetracyclines (intrinsic dental staining), aminoglycosides (nephrotoxicity and ototoxicity), and fluoroquinolones (chondrotoxicity in growing cartilage) is not advocated for these patients. Antibiotics with significant nephrotoxicity should not be used in individuals with kidney disease.

- *Choice of bactericidal antibiotics.* Use of bactericidal agents is generally recommended in the management of acute infection and also for the treatment of immunocompromised patients. It is worth highlighting that bacteriostatic agents are no less effective than bacteriocidal equivalents, and most patients can be adequately managed by the former.
- *Consideration of antibiotic therapy cost.* The cost of therapy may be an important factor in determining the antibiotic regimen. Newer drugs, such as broad-spectrum cephalosporins and carbapenems, tend to be more expensive, whilst older antibiotics, including penicillin and agents that are available as generic drugs, may be cheaper. Intravenous administration is generally more expensive than oral antibiotics.

Principles of antibiotic treatment regimen

Although the treatment regimen should be made in accordance with the manufacturer's recommendation on the proper administration route, dosage, and interval, the following factors should be considered:

- *Dose.* Most infections can be managed with a standard dosage of antibiotic. "High dose" (maximum dose recommended by manufacturer) may be advocated if an infection is severe or progressing rapidly, if the involved site has insufficient blood supply or if a patient is immunocompromised.
- *Time intervals.* Strict adherence to the dosing interval recommended by the manufacturer is critical. However, patients with pre-existing renal disease and subsequent decreased antibiotic clearance might require longer intervals between doses to avoid possible excessive plasma levels and a resultant increase in toxicity reactions.
- *Route of administration.* Antibiotics are commonly administered orally because it is easy, non-painful and cost effective. However, the level of drug absorption in the gastrointestinal tract varies widely between individuals. In addition, various factors can affect drug absorption. Intravenous administration may ensure sufficient and consistent level of antibiotic in plasma and infection site. In the case of severe infection or infection with a high risk of serious complication, antibiotics should be administered intravenously. An intravenous antibiotic is also recommended in patients with trismus or difficulty in swallowing.
- *Duration.* Once antibiotic therapy starts, the antibiotic should be administered for an adequate period. Antibiotic treatment is recommended for an additional 2–3 days after clinical resolution of an infection has occurred to avoid recurrence. Osteomyelitis, sinusitis, and suspected actinomycosis may require longer administration, even after clinical signs and symptoms have disappeared.

Consideration of side-effects

Likely side-effects

If an indication of a side-effect appears, change of the antibiotic should be considered. Hypersensitivity (skin rash) and abdominal symptoms (nausea, vomiting, abdominal cramping, loose stool, and diarrhea) are common side-effects. These might occur even if the patient has previous experience of the same antibiotic without side-effects. A loose stool and the occurrence of diarrhea are usually associated with disrupted microbial homeostasis in the gastrointestinal tract, and once administration of the antibiotic ceases, these side-effects may resolve spontaneously. Serum enzyme concentrations often fluctuate to unacceptable levels, indicating deterioration in hepatic or renal function.

Anaphylaxis
